A Model of the Trade and Government Sectors in Colonial Economies

By THOMAS BIRNBERG AND STEPHEN RESNICK*

This study examines historically and quantitatively the process of colonial development for selected economies of Asia, Africa, and Latin America. A simultaneous equations model is applied to each country from about the start of the twentieth century until the outbreak of World War II in an attempt to identify those forces which made these economies dependent on international trade. A principal objective of this research is to construct and apply a structural model of aggregate behavior which explains the development pattern of several countries in different geographical areas. The sample countries include those experiencing overt colonial control such as Ceylon, India, Jamaica, Nigeria, Philippines, and Taiwan, as well as Cuba, Chile, Egypt, and Thailand where foreign influence and control were perhaps more subtle but no less important in determining economic activity. Our analysis does not intend nor does it show the actual degree or level of exploitation or which groups within which countries benefitted or lost from the colonial relationships.

From about the end of the nineteenth century onwards, economic development in these countries took on a new direction with the extensive penetration of Western commodities, organization, and control, ushering in the era of the export economy.[1] The model measures these external forces through such variables as real income and prices within the developed world which shifted the export demand function facing the colony. This historical development was also characterized by internal colonial government expenditures, directed towards the promotion of the export economy. The effect was a rightward shift of the colonial export supply function.[2] Colonial export prices are thus shown to be endogenous and determined simultaneously by expenditures of the colonial government and also by the developed countries' demand characteristics and trade policies. This suggests that previous explanations of colonial development which have omitted the government as an explicit variable have been misspecified.

The paper is divided into the following three sections: Section I presents the econometric model and summarizes the estimation method used; the empirical results are presented and discussed in Section II; and the last section evaluates the results using dynamic simulations.

* Assistant professor, Yale University and professor, University of Massachusetts, respectively. Portions of this research were financed by funds provided by the National Science Foundation, GS-2804. However, the views expressed in this paper do not necessarily reflect those of the Foundation. Ignazio Cocco, Janet Farooq, and Robin Kibuka provided valuable research assistance in the preparation of this paper.

[1] We selected countries for which we could collect reliable and consistent data going at least as far back as the start of the twentieth century. The sample period for each country is as follows: Ceylon, 1897–1938; Chile, 1890–1938; Cuba, 1903–1937; Egypt, 1891–1937; India, 1890–1936; Jamaica, 1886–1938; Nigeria, 1901–1937; Philippines, 1902–1938; Taiwan, 1904–1936; and Thailand, 1902–1936. A data set for each country was collected from original country and colonial sources listed in the bibliography and is available on request from the authors. Considerable effort was devoted to constructing the data set in order to have a consistent time-series not only to insure reliable estimates but also to make intercountry comparisons. Several countries which could have been included in our sample were rejected because of the quality of their original data.

[2] For a theoretical model describing the role of the government sector, see Stephen Hymer and Resnick.

I. The Model

A basic circular structure underlies a system of five behavioral equations, specified in double logarithmic form,[3] and five definitional equations which together describe the trade and government sectors of a colonial economy. Colonial government expenditures are directed toward promoting the growth of real exports which, in turn, pay for real imports. The expansion of exports and imports generate directly and indirectly revenues for further government expenditures which continue the growth process and complete the circular structure of the model. Changes in real income, prices, and trade policies within the developed world affect the colonial structure through the developed countries' demand for raw materials and food.

A. *The Trade Sector*

Supply and demand equations for real exports along with a market clearing equation act together to describe the economic interrelationship between colony and colonizer. The trade sector is completed by a colonial demand equation for real imports and by definitional equations for nominal exports and imports.

Equation (1) determines the principal commercial activity of the colonial economy which is the supply of real exports.[4]

$$(1)\quad \ln X_{S_t}^R = a_0 + a_1 \ln Px_t + a_2 \ln Pm_t + a_3 \ln \sum_{i=1}^{\infty} G_{t-i}^R + a_4 \ln X_{S_{t-1}}^R + a_5 D_{S_t}$$

where:

X_S^R = the supply of total real commodity exports from the colony.

Px = the colony's Paasche export price index (1913 = 1).[5]

Pm = the colony's Paasche import price index (1913 = 1).

$\Sigma_{i=1}^{\infty} G_{t-i}^R$ = the lagged value of accumulated real government expenditures in the colony.[6] In the discussion to follow, this variable will be denoted *ARGE*.

D_S = a dummy variable reflecting the impact of exogenous events upon the colony's supply function.

This aggregate supply equation assumes that a composite commodity, real exports, depends upon a corresponding export price index. A priori the sign of the export price coefficient a_1 is expected to be positive.[7] Import prices influence real exports in two ways: the costs of production are assumed to be represented by this index since these economies were dependent on the interna-

[3] The double logarithmic form will provide a linear linkage between the model's real and nominal variables, and the estimated coefficients will be elasticities. Linear specification was tried and was found to yield highly inferior estimates, because of multiplicative rather than additive errors.

[4] For ease of exposition, the error terms in all the behavioral equations in this section have been omitted.

[5] The Paasche export and import price indices were specially calculated for this study. These indices were calculated using the largest bundles of goods for which consistent and reliable quantity and value data were available. Paasche indices rather than Laspeyres or Fisher Ideal indices were used because the composition of the commodity bundles changed more rapidly than did prices. The indices were linked using backward bases because exporters respond to current prices relative to past prices, not relative to future prices. The linkages of the indices were designed to account for the principal changes in the composition of the commodity bundles.

[6] The method of calculating this variable is found in the description of the government sector.

[7] a_1 is not only the export price elasticity, but also the terms of trade elasticity, for the supply equation can be rewritten as

$$(1')\quad \ln X_{S_t}^R = a_0 + a_1 \ln P_{T_t} + (a_2 - a_1) \ln Pm_t + a_3 \ln \sum_{i=1}^{\infty} G_{t-i}^R + a_4 \ln X_{S_{t-1}}^R + a_5 D_{S_t}$$

where: $P_T = Px/Pm$ = colony's terms of trade.

tional market for many of their intermediate goods and almost all of their capital goods;[8] and the domestic price of incentive or wage goods in the export sector is assumed to be reflected by this index since their importation often led to the displacement of inferior rural manufactures by superior foreign commodities.[9] For these reasons the sign of the import price coefficient is expected to be negative. Taken together, the export and import prices reflect the macroprofitability of an export economy.

Accumulated real government expenditures enter as a variable because the government is assumed to have been a crucial provider of the necessary infrastructure and social intermediate products associated with the development of an export economy. The growth of trade experienced by these economies would hardly have been possible without the expenditures on harbors, wharves, culverts, road systems, railroads and other public works as well as the investments in administrative infrastructure, in health facilities such as malaria control, in the establishment of order such as an organized police and army establishment, and in various directly productive agrarian activities such as irrigation, artesian wells, disease research for crops, and communication facilities.[10] Thus, accumulated real government expenditures provided the necessary colonial environment in which producers were able to respond to changing market incentives reflected by export and import prices. In a real sense colonial technical progress was embodied within government expenditures, thereby providing the favorable "atmosphere" for the historic development of the export economy.[11] A priori the expected sign of the government variable is positive indicating a rightward shift over time in the supply schedule.[12] And the actual size of the coefficient provides empirical information on the marginal productivity of colonial government expenditures in promoting real exports.

We rejected time as a variable in our model by testing whether lagged accumulated real government expenditures,

$$ARGE \equiv \sum_{i=1}^{\infty} G_{t-i}^{R}$$

was a time variate in the supply equation. First, we replaced *ARGE* with time, and the results contained incorrect signs and high standard errors. Then, we included both *ARGE* and time, and the time variate was insignificant while *ARGE* remained significant. The main reason that *ARGE* is not a proxy for time is because it does not grow linearly. In particular there exist many substantial differences between the growth rates of G_t^R for various subperiods of the estimation period.

Lagged real exports were introduced into equation (1) to test for the possibility that there was a difference between the short- and long-run supply response. The supply equation was estimated with and

[8] One might reasonably assume that domestic labor was available in unlimited supply for export production.

[9] See Resnick (1970) for such a model of trade behavior.

[10] Government expenditures are not disaggregated by category basically because such a breakdown was available only for a few countries. Even if a consistent breakdown was available for all the colonies, there is no theory suggesting what was an export development expenditure and what was not. The only exception to this approach was to subtract expenditures neither directly nor indirectly connected with the development of an export economy, such as the royal household expenditures in Thailand.

[11] Private investment was omitted from the model not only because data were not available, but also because historically government expenditures were complements to or necessarily preceded private investment. In this sense, government expenditures provided the "big push" for the development of the export economy.

[12] We explored the specific question of the time pattern of governmental impact by estimating equation (1) using alternative distributed lag structures. These estimates yielded results inferior to those derived using *ARGE*.

without X^R_{t-1}, and we leave this choice of specification as an empirical question.

Equation (2) explains the demand for real exports.[13]

$$(2)\quad ln\, X^R_{D_t} = b_0 + b_1\, ln\, Px_t + b_2\, ln\, Y^R_t + b_3\, ln\, Pd_t + b_4\, ln\, X^R_{D_{t-1}} + b_5 D_{D_t}$$

where:

- X^R_D = the demand for total real commodity exports.
- Y^R = real *GNP* in the developed country; for some countries industrial production, Q, is used.
- Pd = the domestic price level in the developed country; when Y^R appears as a variable, Pd is the implicit *GNP* price deflator; when Q is used, a Pd was appropriately selected to reflect the commodities traded as either an import price index, or a price index of raw materials.
- D_D = a dummy variable reflecting the effect of exogenous events on the developed country's demand function.

As with the supply equation, we specify a standard distributed lag formulation.

The colony is not assumed to be a price taker; rather the market clearing equation (3) holds.

$$(3)\qquad ln\, X^R_{S_t} = ln\, X^R_{D_t}$$

Export prices are then endogenous to the colonial trade system. This assumption is in contrast to much of the development literature where export prices are assumed implicitly to be exogenous to the developing world.

The assumption of an exogenous export price was empirically tested by estimating the reduced form equation for the export price. Exogenous variables in both the supply and demand equations for each country were significant and, therefore, were required to explain the export price. Thus the assumption of an exogenous export price was rejected,[14] and the estimation of a demand equation as well as a supply equation using simultaneous equations methods was necessary.

The political and economic relationship between the colony and the developed country often led to a fairly high percentage of the former's total commodity trade being carried on with the developed country and its other colonies (see Table 1). Exports to these other colonies were either for transshipment (for example, entrepôt trade with Hong Kong and Singapore) or for direct consumption in these colonies. The model assumes that the economic activity of these other colonies is reflected by and can be measured by that of the developed country. Therefore, the specification of equation (2) is based upon the empirical observation that colonial trade was bilateral in nature which, in turn, reflected the bilateral political relationship that emerged over time. For these reasons, competitive prices for alternative sources of export supply do not appear in the developed country's aggregate demand schedule. A domestic price level is included to reflect the substitution between domestic and imported goods.

The incomes and prices of the United Kingdom, United States, and Japan are assumed to be the main driving forces or instruments affecting the economic ac-

[13] For countries with a variable exchange rate, the demand price is a new variable Px' defined by the additional equation, $ln\, Px' = ln\, Px + ln\, \pi$, where π is the exchange rate of the colony's currency relative to that of the developed country to which it was tied.

[14] The importance of specifying the export price as endogenous was originally motivated by estimates of the supply equation with the export price as exogenous. These estimates yielded negative, rather than positive, export price coefficients for most countries.

TABLE 1—DISTRIBUTION OF EXPORTS FOR SELECTED YEARS

	Developed Country	Percentage of Export Trade with Developed Country 1900[a]	1913	1925	1938[b]	Instruments Corresponding to Developed Country[c]
Ceylon	*U.K.*+colonies	78.3	58.0	52.2	72.1	Y^R_{UK}, *LIMIT*
	U.S.	7.0	16.5	29.9	12.6	*CAR*
Chile	*U.S.*	3.9	21.0	39.2	30.0	Q_{US}, P^{mn}_{US}, *RESTR*
	U.K.	73.5	39.5	34.6	26.0	
Cuba	*U.S.*	76.8	79.9	74.6	80.7	Q_{US}, P^m_{US}, *QUOTA*
Egypt	*U.K.*	54.5	42.6	43.5	30.9	Y^R_{UK}, P_{UK}, *WWI*
India	*U.K.*+colonies	59.1	39.4	34.1	45.7	Q_{UK}, P_{UK}
Jamaica	*U.K.*+colonies	23.2	24.8	48.6	85.0	Q_{UK}, P_{UK}
	U.S.	63.8	57.4	40.7	3.7	*RESTR*
Nigeria	*U.K.*	31.4	50.9	54.7	50.0	Y^R_{UK}, P_{UK}
	Germany	55.8	41.8	21.3	17.7	*WWI*
Philippines	*U.S.*	40.0	34.4	73.0	77.0	Y^R_{US}, P_{US}, *QUOTA*
Taiwan	Japan	60.0	75.7	82.0	89.4	Y^R_{JP}, P_{JP}, *WWI*
Thailand	*U.K.*+colonies	85.5	83.2	74.6	79.0	Y^R_{UK}, P_{UK}

[a] The initial year used for Cuba is 1903, for Nigeria is 1901, for Philippines is 1904, and for Thailand is 1901.
[b] The final year used for Chile, Cuba, and Egypt, 1937; for India, 1936; and for Taiwan, 1935.
[c] For definitions see Appendix.

tivity of their respective colonies (see Table 1). While the model focuses upon the principal trading relationships that emerged historically, adjustments to this approach are made when the export trade pattern showed an obvious change in direction. For Ceylon, the variable *CAR* reflects the demand for rubber by the United States after 1905. In Chile, even though the United States and the United Kingdom were the major trading partners, copper exports were controlled by three *U.S.* companies. The *U.S.* income and price variables are taken then as the main determinants of the demand function. For Jamaica, the dummy *RESTR* accounts for the dramatic decline of its trade with the United States after the imposition of the Hawley-Smoot Tariff of 1930. For Nigeria, the dummy *WWI* measures the impact of the complete cutoff of its trade with Germany.

The growth in real exports had as its dual the growth of real imports. The increased specialization of the colonial economy was reflected by a shift of resources out of traditional activities into commercial ones. Correspondingly, the demand for foreign consumer and intermediate commodities expanded. Here, the opposite of an import-substitution policy was being pursued. Colonial policy was clearly biased towards the promotion of exports rather than indigenous manufacturing, and the resulting decline of traditional industry associated with the precolonial agrarian society was replaced by the expansion of and reliance on imported manufactures.

Equation (4) describes the demand function for imports in real terms.

$$(4) \qquad ln\, M_t^R = c_1\, ln\, X_t^R + c_2\, ln\, Pm_t + c_3\, ln\, Px_t + c_4 D_{M_t}$$

where:

M^R = total real commodity imports by the colony.

D_M = a dummy variable reflecting the impact of exogenous events upon the colony's import function.

The following definitional equations for nominal commodity imports M_t and nominal commodity exports X_t complete the trade sector.

$$(5)\qquad ln\ M_t = ln\ M_t^R + ln\ Pm_t$$

$$(6)\qquad ln\ X_t = ln\ X_t^R + ln\ Px_t$$

In equation (4) the coefficient c_1 measures the increase in real imports caused by an increase in real exports. This coefficient also provides a measure of the nominal trade balance. If $c_1 < 1$, then the colony ran a nominal trade surplus, while if $c_1 > 1$, it ran a nominal trade deficit.[15] The coefficient c_2 is the import price elasticity of demand by the colony for developed countries' goods. The coefficient c_3 measures the shift of the demand schedule for real imports as export prices change. A priori, we expect the sign of c_2 to be negative and the sign of c_3 to be positive.[16]

B. *The Government Sector*

The government sector has two behavioral equations, the generation of nominal revenues (7) and the expenditures from that revenue (8).

$$(7)\quad ln\ R_t = d_0 + d_1\ ln\ X_t^R + d_2\ ln\ M_t + d_3 D_{R_t}$$

$$(8)\quad ln\ G_t = e_1\ ln\ R_t + e_2\ ln\ G_{t-1} + e_3 D_{G_t}$$

where:

R = total nominal revenues generated in the colony.
M = the colony's total nominal commodity imports.
G = nominal colonial government expenditures.
D_R; D_G = dummy variables reflecting the impact of exogenous events upon the colony's government revenue and expenditure functions, respectively.

[15] To derive this conclusion, rewrite equation (4) in terms of nominal imports and nominal exports as

$$(4')\qquad ln\ M_t = c_1\ ln\ X_t + (c_2 + 1)\ ln\ Pm_t + (c_3 - c_1)\ ln\ Px_t + c_4 D_{M_t}$$

[16] With both the import and export prices scaled equal to one in 1913, the coefficients c_2 and c_3 describe how these prices change the nominal trade balance of the colony relative to that in 1913.

The expansion of real exports is assumed to generate revenues directly from specific export taxes or indirectly given that taxable real economic activity in the colony was in one way or another tied to real export activity. Revenues from nominal imports were derived directly from import duties and indirectly from taxes on commercial import activity. The expenditure equation (8) can be derived from a revenue expectation model, where government spending in the current period depends on expected revenue. An alternative derivation of equation (8) is that government expenditures are divided between recurrent expenditures, $e_2\ ln\ G_{t-1}$, and current expenditures, $e_1\ ln\ R$.

Real government expenditure in a given year is defined as[17]

$$(9)\qquad ln\ G_t^R = ln\ G_t - ln\ Pm_t$$

The price of imported goods is thus assumed to reflect the cost of government expenditures because government capital goods were usually imported, and government employees, particularly colonial officers, were dependent on imports to maintain their standard of living. Lagged accumulated real government expenditures (*ARGE*) are then calculated using the inventory formula[18]

$$(10)\quad ARGE \equiv \sum_{i=1}^{\infty} G_{t-i}^R = \sum_{i=1}^{\infty} G_{T_0-i}^R + \sum_{i=T_0}^{t-1} G_i^R$$

[17] For some countries, we added to government expenditures in equation (9) the relatively small value of public works expenditures financed from borrowing abroad.

[18] For several reasons, accumulated real government expenditures were not depreciated. There exists no a priori information on the actual depreciation of these expenditures. If they are a measure of colonial technical progress, then no depreciation rate should be used. In addition, we carefully checked the sensitivity of our supply equation estimates against those with assumed rates of depreciation. For a range of possible rates of 1 to 4 percent, we found small changes in the estimates. As the depreciation rate rose above 4 percent, the estimates became increasingly inferior.

where: T_0=earliest year of data for G_t^R. $\sum_{i=1}^{\infty} G_{T_0-i}^R$ is the initial stock of accumulated real government expenditure which was calculated by first estimating the regression equation for the growth rate of G^R:

$$\ln G_t^R = a_0 + a_1 t \qquad t = T_0, T_0+1, \ldots, \tau$$

where τ is selected as the year with the longest consistent pattern of growth of G^R. Let $\hat{a}_0$ and $\hat{a}_1$ be the estimated values of a_0 and a_1. Then

$$\sum_{i=1}^{\infty} G_{T_0-i}^R = \sum_{i=1}^{\infty} e^{\hat{a}_0} e^{(T_0-i)\hat{a}_1} = e^{\hat{a}_0+T_0\hat{a}_1} \sum_{i=1}^{\infty} e^{-\hat{a}_1 i}$$
$$= e^{\hat{a}_0+T_0\hat{a}_1}/(e^{\hat{a}_1} - 1)$$

is the estimated initial stock of accumulated real government expenditures.

C. *Estimation Method*

Equations (1) through (10) constitute a system of ten equations in ten unknowns, namely X_S^R, X_D^R, Px, M^R, X, M, R, G, G^R, and $ARGE$. Initial estimates of the model using instrumental variables revealed a well-defined pattern of serial correlation in the plotted residuals of most equations. This serial correlation posed serious problems for making reliable cross-country comparisons, for distinguishing between distributed lags and autoregressive errors, and for judging the performance of the model in explaining the observed development pattern.

An estimation method described in the econometric part of the Appendix was used to solve these problems of autocorrelated errors in a simultaneous equation system. All current and lagged endogenous variables in the autoregressive model were treated as endogenous. Therefore, these variables were instrumentally adjusted taking into account the structural ordering of the model. Using an iterative method, the model yielded consistent estimates of the equation parameters. This method always converged to a value of the autoregressive parameter ρ that satisfied the condition that its absolute value did not exceed one. The method actually removed the first-order serial correlation pattern in the data.[19] Finally, the iterates yielded estimates of the parameters with correct signs and relatively low standard errors.

II. The Results

The estimates of the five structural equations for each of the ten countries are reported in Appendix Tables 1 through 5. All the signs of the estimated coefficients are correct, and the standard errors of the coefficients and of the equations are rather low.[20]

We find lagged real exports X_{t-1}^R appearing as an explanatory variable indicating the presence of a lagged adjustment process in the supply equations of Cuba, Ceylon, Nigeria, and Taiwan, and in the demand equations of Chile, Nigeria, and the Philippines. For the remaining supply and demand equations, lagged real exports did not appear significant and it was dropped as an explanatory variable.

The estimated export price coefficients of the supply equations indicate inelastic aggregate supply schedules in colonial economies. The elasticity estimates vary in magnitude from .142 in Nigeria to .536 in Jamaica, with an average of .315. These are short-run supply elasticities for all countries and also long-run supply elasticities for the six countries where no dis-

[19] While this conclusion is based upon examination of the plots of the estimated residuals of the fifty equations estimated, one imperfect indicator of the degree of improvement is given by the Durbin-Watson statistic. Omitting the eight equations for which no autoregressive adjustment was needed, the average $D.W.$ statistic was 1.23 before and 1.94 after the adjustment.

[20] We have reported t-values and the R^2 statistics because they are usually expected, even though there are qualifications about their applicability in a simultaneous equation system.

tributive lag process was found. For the four countries in which X^R_{t-1} appears, the average long-run elasticity is .880 ranging from .281 in Nigeria to 1.92 in Ceylon. If Ceylon is excluded on the grounds that its exports were comprised primarily of output from tea and rubber estates, then the estimated aggregate supply elasticity for a colonial economy is inelastic in both the short and long run.[21]

The elasticity of demand for aggregate real exports is also typically inelastic with the average export price coefficient in the demand equation of $-.512$ in the short run for all ten countries. The long-run elasticity averages -1.15 for three countries in which an adjustment process is present. If Chile is excluded on the grounds that the demand for the two main exports, copper and nitrate, is elastic, then the average falls to $-.41$ in the short run and $-.95$ in the long run (for Nigeria and the Philippines).

The relatively inelastic supply and demand schedules for a colonial economy when both curves were quite shiftable produced rather dramatic changes in the price of exports. Shifts in the supply schedule are measured by the coefficients of the import price and accumulated real government expenditures. The average coefficient associated with the government variable is .47 and with the import price, $-.35$; for the four countries with an adjustment process, the respective long-run coefficients are 1.2 and $-.8$. India has the lowest long-run elasticity associated with government expenditures followed by Egypt and then Thailand. In fact, these three countries seem to be in a relatively low export-promoting governmental productivity group compared to the other seven countries; the average long-run governmental elasticity being 1.00 for the latter group and .31 for the former. Almost one-half of the Indian budget was devoted on the average to military expenditures for the period and thus a low coefficient is not surprising. Although Egypt and Thailand were not colonies in the legal sense, their respective economies were as much subject to *U.K.* influence as that of India. Egypt had the slowest growth rate of real exports of all ten countries and her resources seem to have been increasingly focused on the required repayment of previous international loans rather than devoted toward development expenditures.[22] The Thai government was effectively constrained from controlling and utilizing governmental expenditures for productive investments by *U.K.* financial control.[23]

This result shows that the government must be included in explaining the development of a colonial export economy and that to ignore or omit this relationship would lead to a major error of misspecification. These conclusions do not depend upon the size of the coefficient of accumulated real government expenditures. The impact of these expenditures is equally important in explaining the low export growth of India which had the lowest coefficient as well as in explaining the high export growth of Ceylon and the Philippines which had the highest coefficients.

Shifts in the demand schedule facing the colony are measured by the coefficient of real income and domestic prices in the developed country. The average income elasticity of demand for colonial goods is .83 in the short run and 1.39 in the long run for those three countries in which X^R_{t-1} appears. For all ten countries the average long-run income elasticity is 1.09 which indicates the importance of income growth in the developed countries on ex-

[21] Of course, within the export sector, there may be significant shifting of resources out of one export to another as relative export prices change.

[22] See Charles Issawi and A. E. Crouchley for further discussion.

[23] See James Ingram.

port growth in the colonial countries. The average elasticity of substitution between home and colonial commodities in the developed countries is .45 in the short run and, for the latter three countries, 1.33 in the long run. Examining these substitution elasticities by colonial blocs suggests that those countries which were under direct or indirect United States influence had the highest substitution effects as compared to the United Kingdom bloc or to Japan (for the case of Taiwan). There was more internal substitution over the period within the United States (copper for Chile and cane sugar for Cuba and the Philippines) than for either the United Kingdom or Japan. The model would predict, then, that *ceteris paribus*, a fall in *U.S.* prices would shift its demand schedule for colonial goods to the left more than an equivalent fall in the prices of the United Kingdom or Japan. For this reason the world depression of the 1930's had a more dramatic effect on Chile, Cuba, and the Philippines compared to the other seven countries. In contrast, the real income effects of the United Kingdom and Japan were more important than their price levels in influencing real export activity in their trade dependent countries.

The remaining variables in the supply and demand schedules are the dummy variables, which are specific to the economic history of the country such as the impact of an imposed tariff, quota, restriction scheme, or the influence of the First World War. The dummies all have the proper sign and are generally important in magnitude. The depressing effects of the restrictive trade policies pursued by the United States during the 1930's are measured by the dummies *RESTR* for Chile, and *QUOTA* for both Cuba and the Philippines. Since prices and real income were falling in the United States during the Great Depression, the imposition of these restrictions on trade compounded the difficulties experienced in these three countries as compared to countries tied to the United Kingdom or Japan. Interestingly enough, the trade restrictions put upon the Philippines were not as severe and came somewhat later in the depression years as compared to those for Cuba and Chile. This partial evidence suggests, at least for those countries linked to the United States, that legal colonialism as exemplified by the Philippines acted to mitigate the impact of United States policies during the 1930's.

The results indicate that similar dummy variables used in different countries need not have the same sign. For example, the effects of World War I benefitted the supply of real exports from Taiwan to Japan, whereas Nigerian trade suffered from the effects of the war because trade with Germany, one of its main export markets, was completely cut off and did not resume until 1922.

In the import equation, the average coefficient of real exports was .98, which indicates that, *ceteris paribus*, the growth of real exports in each colony did produce a corresponding demand for imported commodities. Moreover, this average coefficient indicates that the colonies ran a nominal trade surplus over this historical period which agrees with their actual balance of trade data. Jamaica was the only country with a coefficient greater than one, and Thailand's coefficient is the lowest of all ten countries. Both of these results are consistent with their actual trade data which show Jamaica as the only country with a nominal trade deficit and Thailand with the relatively largest nominal trade surplus. Finally, the average import price elasticity of demand was $-.42$, thus once again revealing inelastic demand schedules but this time for imports of the developed countries' goods.

The revenue equation shows that the average contribution of real exports to

nominal revenues was slightly higher (.59) than that of nominal imports (.52). However, the marginal contribution of real exports varies from a low of .230 in Thailand to a high of 1.203 in Chile (where imports were not effectively taxed), while the marginal contribution of nominal imports varies from a low of .191 in Cuba to .626 in Jamaica.

A measure of the total tax effort is the sum of the coefficients of X^R and M in the revenue equation. The average sum for the ten countries is 1.01 which suggests a constant returns to scale revenue function. However, Thailand and Taiwan have an average sum of tax coefficients of .61. Compared to the other eight countries where the average sum is now 1.12, the colonial tax effort for these two countries was not strong enough.

Some of the dummy variables in the revenue equation measure changes in the tax effort such as the imposition of an income tax on copper in Chile from 1926 to 1938; the use of the new tariff schedule in Egypt from 1931 to 1938, in India from 1931 to 1937, and in Thailand from 1927 to 1938. The coefficients associated with these dummy variables indicate that for Chile and India the incremental revenues generated were large compared to those for Egypt and Thailand. Changes in accounting practices of the railroads are measured by the dummy *NET* in Ceylon, India, and Nigeria and the dummy *RAIL* in Jamaica.

Examining the results of the expenditure equation, the average short-run revenue elasticity is .62 and the average elasticity associated with lagged expenditures is .38. For each of the ten countries, the resulting long-run revenue elasticity is very close to one. This value is consistent with the underlying data which indicate that each colonial government did indeed run a balanced budget in the long run. There is significant variation in the distribution between current and recurrent nominal expenditures for the ten countries. Chile, India, and Taiwan form one bloc where expenditures were financed almost entirely out of current revenues. For the other seven countries, recurrent expenditures were much more important.

III. Concluding Comments

A dynamic simulation of the model for each country for the full estimation period was performed to judge its performance in explaining the observed development pattern and to check the reliability of our estimates. An examination of the simulation plots for each country revealed no systematic divergences between the calculated and observed values of each variable. For example, the dynamic simulations had an average standard error of .1052 for real exports. This average compares quite well with the average standard errors of .1078 in the estimated supply equations and of .1035 in the estimated demand equations. As we have found, the historic pattern of export prices was very volatile due to relatively price inelastic and quite shiftable colonial supply and demand schedules. Thus a favorable test of the model is that the dynamic simulation of the export price for each country closely corresponded with the actual fluctuations of the export price, with .1458 as the average standard error. The simulation also indicated a check of the method of calculating accumulated real government expenditures, for which the standard error was .0436 and the average absolute residual for the last year was .0362. These dynamic simulations provide the final empirical support for the specification of the theoretical model and for the accuracy of the structural estimates.

We have found that there was a similar process of colonial development, as specified by our structural model. This model has identified common internal and ex-

ternal forces which transformed colonial countries in a similar pattern during the period of our study. A major finding is the role of government expenditures in promoting the growth of colonial export supply. We have also verified the role of developed countries' demand variables and trade policies, and we have measured how these external forces affected colonial export demand. Although this study described a similar development process, the results indicate significant differences in the coefficient estimates[24] which explain this common process. In fact, it is these very differences which explain why the same model works well in explaining the wide range of observed export and government growth rates. Thus, to understand the similar, but not identical, historical process of colonial development requires analyzing the common circular structure of their trade and government sectors as well as recognizing the diversity within that structure.

Appendix

Econometric Method

The estimation method used in this paper considers a set of K simultaneous equations

$$\text{(A.1)} \qquad Y\Gamma + Y_{-1}A + XB = U$$

where there are K endogenous variables, Y; K lagged endogenous variables, Y_{-1}; and M exogenous variables, X. For T observations, then, Y and Y_{-1} are TxK matrices, and X is a TxM matrix. Γ, A, and B are matrices of coefficients to be estimated with dimensions KxK, KxK, and MxK, respectively.

Assume the error matrix U follows a first-order autoregressive pattern

$$\text{(A.2)} \qquad U = U_{-1}R + E$$

where U_{-1} is the matrix of U lagged, and U, U_{-1}, and E are TxK matrices. Denoting e_t' as the column components of E, the following assumptions are made:

$E(e_t) = 0 \quad t = 1, 2, \ldots, T$
$E(e_t)(e_t') = \Sigma \quad t = 1, 2, \ldots, T$, Σ positive definite
$E(e_t)(e_\tau') = 0 \quad t, \tau = 1, 2, \ldots, T$, $t \neq \tau$
$plim\ T^{-1}XE = plim\ T^{-1}X_{-1}E = 0$
$plim\ T^{-1}Q'Q$ exists as a fixed, nonsingular matrix where $Q = (X, X_{-1})$
R is a diagonal matrix with elements $|r_{ii}| < 1$, $i = 1, 2, \ldots, K$
$(\Gamma + A)$ has an inverse.

The equations of the model are identified.

Without any loss of generality, let the equation to be estimated be the equation for the first endogenous variable y_1

$$\text{(A.3)} \qquad y_1 = Y_1\gamma_1 + Y_{1_{-1}}\alpha_1 + X_1\beta_1 + u_1$$

where y_1 is a column vector of T observations; Y_1 is a Txk_1 matrix of observations on k_1 other included endogenous variables; $Y_{1_{-1}}$ is a Txj_1 matrix of observations on j_1 included lagged endogenous variables; X_1 is a Txm_1 matrix on m_1 included exogenous variables; and β_1, α_1, and γ_1 are vectors of coefficients to be estimated. The T-component column vectors of error terms, u_1, $u_{1_{-1}}$, and e_1, satisfy

$$\text{(A.4)} \qquad u_1 = \rho_1 u_{1_{-1}} + e_1$$

where ρ_1 is the first diagonal element of R. As the only lagged endogenous variables appearing in this paper's theoretical model are lagged left-hand variables, equation (A.3) can be simplified to

$$\text{(A.5)} \qquad y_1 = Y_1\gamma_1 + y_{1_{-1}}\alpha_1 + X_1\beta_1 + u_1$$

From (A.4) and (A.5), the equation to be estimated is

$$\text{(A.6)} \qquad \begin{aligned} y_1 - \rho_1 y_{1_{-1}} = {} & (Y_1 - \rho_1 Y_{1_{-1}})\gamma_1 \\ & + (y_{1_{-1}} - \rho_1 y_{1_{-2}})\alpha_1 \\ & + (X_1 - \rho_1 X_{1_{-1}})\beta_1 \\ & + e_1 \end{aligned}$$

Outline of the Estimation Procedure

The equation (A.6) can be consistently estimated using the following limited information method.

(i) *Instrumental Adjustment.* Using a set of instrumental variables that include at

[24] This conclusion was statistically verified using covariance analysis.

least X_1 and $X_{1_{-1}}$ and are asymptotically uncorrelated with e_1, instrumentally adjust Y_1, $Y_{1_{-1}}$, $y_{1_{-1}}$, and $y_{1_{-2}}$ and denote their predicted values as, respectively, $\hat{Y}_1$, $\hat{Y}_{1_{-1}}$, $\hat{y}_{1_{-1}}$, and $\hat{y}_{1_{-2}}$.

(ii) *Initial Consistent Estimation.* Estimate equation (A.5) by ordinary least squares using $\hat{Y}_1$ instead of Y_1 and $\hat{y}_{1_{-1}}$ instead of $y_{1_{-1}}$. Denote the estimated coefficients of this regression as $\hat{\gamma}_1$, $\hat{\alpha}_1$, and $\hat{\beta}_1$. By the properties of instrumental variables, these estimates are consistent. A consistent estimate of the residuals u_1 is given by

$$\text{(A.7)} \quad \hat{u}_1 = y_1 - Y_1\hat{\gamma}_1 - y_{1_{-1}}\hat{\alpha}_1 - X_1\hat{\beta}_1$$

A consistent estimator of ρ_1 is given by

$$\text{(A.8)} \quad \hat{\rho}_1 = (\hat{u}_{1_{-1}}{}'\hat{u}_1)/(\hat{u}_{1_{-1}}{}'\hat{u}_{1_{-1}})$$

Thus $\hat{\rho}_1$ is the estimated coefficient obtained by regressing $\hat{u}_1$ on $\hat{u}_{1_{-1}}$.

(iii) *Iterative Procedure.* For any consistent estimator $\hat{\rho}_1$ of ρ_1, estimate (A.6) by ordinary least squares using the instrumentally adjusted endogenous variables, $\hat{y}_{1_{-1}}$, $\hat{Y}_1$, $\hat{Y}_{1_{-1}}$, and $\hat{y}_{1_{-2}}$ instead of $y_{1_{-1}}$ Y_1, $Y_{1_{-1}}$, and $y_{1_{-2}}$, respectively. The estimated coefficients of this regression are denoted by $\hat{\gamma}_1$, $\hat{\alpha}_1$, and $\hat{\beta}_1$, and these estimates are consistent. Use these estimates to calculate successively $\hat{u}_1$ and $\hat{\rho}_1$, using equations (A.7) and (A.8). Starting with the initial consistent estimates of (ii), continue this iterate procedure until the estimates converge.

(iv) *Equation Statistics.* A consistent estimator of e_1 is

$$\text{(A.9)} \quad \hat{e}_1 = \hat{u}_1 - \hat{\rho}_1\hat{u}_{1_{-1}}$$

Calculate the standard error of the equation using

$$\text{(A.10)} \quad \hat{S}_1 = \sqrt{(\hat{e}_1'\hat{e}_1)/T}$$

The estimated variance-covariance matrix of the estimated coefficients is

$$\text{(A.11)} \quad V(\hat{\delta}_1) = \hat{S}_1^2(\hat{Z}_1'\hat{Z}_1)^{-1}$$

where: $\hat{\delta}_1 = [\hat{\gamma}_1, \hat{\alpha}_1, \hat{\beta}_1]$ and $\hat{Z}_1 = [\hat{Y}_1 - \hat{\rho}_1\hat{Y}_{1_{-1}}, \hat{y}_{1_{-1}} - \hat{\rho}_1\hat{Y}_{1_{-2}}, X_1 - \hat{\rho}_1 X_{1_{-1}}]$

Characteristics of the Estimation Procedure

Consistency of the procedure relies on three facts. First, all the included predetermined variables appearing in equation (A.6), namely X_1 and $X_{1_{-1}}$, appear in the list of instruments used in step (i). Second, the equation is assumed to be identified. Third, the set of instrumental variables used are asymptotically uncorrelated with e_1.

In this estimation procedure, the lagged endogenous variables appearing in (A.6), $Y_{1_{-1}}$, $y_{1_{-1}}$, and $y_{1_{-2}}$, are treated as endogenous rather than exogenous. Recalling the discussion by Franklin Fisher, the endogeneity of these lagged variables arises from the fact that they are correlated with the error term, e_1. This argument is particularly applicable here because the lagged left-hand variable appears due to both a distributed lag process and an autoregressive process. If $Y_{1_{-1}}$, $y_{1_{-1}}$, and $y_{1_{-2}}$ are endogenous, then the estimation methods proposed by Ray Fair and Phoebus Dhrymes will yield inconsistent estimators since their methods treat lagged endogenous variables as exogenous.

The instrumental adjustment was done using the structurally ordered instrumental variable method described by Fisher and by Bridger Mitchell and Fisher. In the econometric model, structural ordering emphasizes lagged exogenous variables rather than current exogenous variables in the instrumental adjustment of lagged endogenous variables, while still satisfying the consistency requirement of using X_1 and $X_{1_{-1}}$ as instruments. First regress Y_1, $Y_{1_{-1}}$, $y_{1_{-1}}$, and $y_{1_{-2}}$ on instrument lists of different exogenous variables. Let $\tilde{Y}_1$, $\tilde{Y}_{1_{-1}}$, $\tilde{y}_{1_{-1}}$, and $\tilde{y}_{1_{-2}}$ be fitted values of these regressions. For consistent estimators, then instrumentally adjust Y_1, $Y_{1_{-1}}$, $y_{1_{-1}}$, and $y_{1_{-2}}$ using $\tilde{Y}_1$, $\tilde{Y}_{1_{-1}}$, $\tilde{y}_{1_{-1}}$, $\tilde{y}_{1_{-2}}$, X_1 and $X_{1_{-1}}$ to obtain the predicted values $\hat{Y}_1$, $\hat{Y}_{1_{-1}}$, $\hat{y}_{1_{-1}}$. and $\hat{y}_{1_{-2}}$ of the first step of the estimation procedure.

Definitions of Developed Country Variables and Dummy Variables

Developed Country Variables

- CAR = Motor vehicle factory sales, United States
- P_{JP} = GNP price deflator with 1934–36 = 100, Japan
- P_{UK} = National income price deflator with 1913–14 = 100, United Kingdom

P_{US} = GNP price deflator with 1929 = 100, United States

P^m_{US} = Fisher import price index with 1913 = 100, United States

P^{mm}_{US} = Import price index of crude materials with 1913 = 100, United States

Q_{UK} = Index of industrial production excluding building, United Kingdom

Q_{US} = Index of manufacturing output with 1929 = 100, United States

Y^R_{JP} = Real GNP in millions of 1934–36 yen, Japan

Y^R_{UK} = Real net national income in millions of 1913–14 pounds, United Kingdom

Y^R_{US} = Real GNP in millions of 1929 dollars, United States

Dummy Variables

FIXED = Thailand, tariffs fixed by the Bowring Treaty until 1926, and thereafter increasing tariffs, 1927–37

INCOME = Chile, income tax on copper producers, 1926–38

INFRA = Nigeria, completion of infrastructure projects—railroad to Northern Nigeria and port of Lagos—1917–38

LIMIT = Ceylon, international restriction scheme on rubber exports, 1935–38

NET = Change from gross to net railway revenues in Ceylon, 1929–38; India, 1906–36; Nigeria, 1927–38

QUOTA = Cuba, *U.S.* import sugar quotas and tariffs, 1930–37; Philippines, *U.S.* import sugar quotas, 1935–38

RAIL = Jamaica, government takeover railroads, 1900–38

RESTR = *U.S.* import tariffs and restrictions in Chile, 1932–38; in Jamaica, 1932–38

TARIFF = New tariff schedules in Egypt, 1931–38; India, 1931–37

WORKS = Ceylon, expenditure includes public works expenses, 1916–24

WWI = Effects of World War I in Ceylon, 1915–18; Egypt, 1915–18; Nigeria, 1915–21; Taiwan, 1915–19

Heavy and Light Industry in Economic Development

By MORRIS TEUBAL*

Accepted doctrine regarding the choice between light (labor-intensive) industry and heavy (capital-intensive) industry in the early stages of industrialization reflects in part the conclusions of the neoclassical Factor Proportion Theorem and the Rybczynski Theorem.[1] According to these, in a small economy (i.e., one which has no influence on world prices) under free trade, light industry must necessarily come into existence before heavy industry.

This prescribed optimum industrialization sequence is not necessarily in accordance with the experience of European industrialization; Alexander Gerschenkron, in particular, has pointed out that there is a variety of industrialization patterns including instances of initial emphasis on heavy industry. Our purpose here is to present a model in which the optimum strategy may be initially based on either light or heavy industry, depending on the factor endowment, technology, and factor accumulation patterns of the country involved. It is hoped in this way to contribute to a better understanding of the factors which should be taken into account when devising desirable industrialization strategies for today's developing countries.[2]

The analysis is carried out in terms of a three-sector neoclassical model of an economy which faces fixed, exogenously determined prices for all goods. Except for the explicit introduction of an agricultural sector, I follow the standard Hecksher-Ohlin model in assuming free trade with no transport costs, two factors of production (labor and capital), constant returns (except in the primary sector), a given technology, and no externalities. Thus, it resembles the model presented in my previous paper except that the relative price of the primary good is determined exogenously in world markets (small economy assumption) instead of being determined by the quantity of exports (medium-sized economy assumption).[3]

The conclusions about dynamic comparative advantage that emerge from the model are quite clear-cut despite the fact that an accumulation mechanism is not explicitly considered. In particular, heavy industry may be the optimum starting point for industrialization, as pointed out in my earlier paper. This possibility is greater the higher (lower) the initial capital stock (labor force), the higher (lower) the rate of capital accumulation (population growth) and, everything else equal, the higher the returns to scale in the primary sector (within the class of decreasing returns to scale production functions).[4]

* Lecturer, department of economics, Eliezer Kaplan School of Economics and Social Sciences, Hebrew University.

[1] See, for example, R. W. Jones and T. M. Rybczynski.

[2] In what follows I draw on an earlier article published in 1971.

[3] This guarantees the independence of the allocation decision from the saving or accumulation decision. In the previous model this was not possible; there, an increase in investment is in part financed by an increase in exports of primary goods, which reduces their relative price and induces resource reallocation.

[4] These results are an extension of those obtained previously. In that paper a constant labor force was assumed although an explicit, utility maximizing mechanism of accumulation was postulated. Some proofs relevant to both papers are given in the Appendix.

I

Technology

The technology of the three sectors is described in my 1971 paper. There are two augmentable factors of production—capital and labor—and the production functions of the industrial sectors (B and C for light and heavy industry, respectively) are homogeneous of degree one, while that of the primary sector A, is of the decreasing returns to scale variety (because land is nonaugmentable and/or of declining fertility). Let K_i, L_i, k_i, y_i be the capital input, labor input, capital-labor ratio, and output of sector i, respectively. Then

$$(1) \qquad y_a = F^a(K_a, L_a) \equiv F^a(k_aL_a, L_a)$$

$$(2) \qquad \lambda F^a(K_a, L_a) > F^a(\lambda k_aL_a, \lambda_a) \qquad \text{for } \lambda > 1$$

$$(3) \qquad y_i = F^i(K_i, L_i) = L_if_i(k_i)$$

It is further assumed for the primary sector that (i) any increase in scale (that is, and increase in L_a for constant k_a) reduces the marginal product of *both* factors; (ii) the marginal product of one factor, say labor, increases to infinity as the scale approaches zero; and (iii) factors are complementary. Let $F_J^a(J=K, L)$ be the marginal product of factor J in agriculture and F_{KK}^a, F_{LL}^a, F_{KL}^a the direct and cross second-order derivatives of the production function in this sector. Then, assumptions (i)–(iii) imply

$$(4) \qquad \frac{d}{dL_a}(F_J^a) = k_aF_{JK}^a + F_{JL}^a < 0 \qquad (J=K, L)$$

$$(5) \qquad \lim_{\substack{L_a\to 0\\ k_a>0}} F_L^a(k_aL_a, L_a) \to \infty$$

$$(6) \qquad F_{KL}^a = F_{LK}^a > 0$$

Equation (4) defines a subclass of decreasing returns to scale production functions, i.e., it is sufficient for condition (2) to hold. Equation (5) guarantees that for a positive world price of agricultural goods, agricultural output is necessarily positive.[5] Finally assume $k_c > k_b > k_a$.

Maximization

Let Y, K, L be national income at world prices in terms of heavy-industry goods, total capital, and total labor, respectively. At any moment of time, the objective is an allocation of (K, L) which maximizes Y, i.e.,

$$\max_{(K_i,L_i)} Y = p_aF^a(K_a, L_a) + [qF^b(K_b, L_b) + F^c(K_c, L_c)]$$

subject to $K_b + K_c = K - K_a$ and $L_b + L_c = L - L_a$, where p_a, q are the world prices of agricultural and light-industry goods in terms of heavy-industry goods.

The first-order conditions for a maximum under the assumption that all three goods are being produced in positive quantities, i.e., that the economy is in the nonspecialization phase, can be grouped as follows:

i. *Marginal productivity conditions of the industrial sectors*

$$(7) \qquad q\frac{\partial F^b}{\partial K_b}(k_b) = \frac{\partial F^c}{\partial K_c}(k_c) = r$$

$$(8) \qquad q\frac{\partial F^b}{\partial L_b}(k_b) = \frac{\partial F^c}{\partial L_c}(k_c) = w$$

ii. *Marginal productivity conditions of the agricultural sector*

$$(9) \qquad p_aF_K^a(K_a, L_a) = r$$

$$(10) \qquad p_aF_L^a(K_a, L_a) = w$$

iii. *Resource constraints*

$$(11) \qquad k_bL_b + k_cL_c = K - K_a$$

$$(12) \qquad L_b + L_c = L - L_a$$

[5] Assumption (ii) or equation (5) is sufficient but not necessary for the purpose of the paper. The fact that it guarantees a positive output of agricultural goods simplifies the exposition without affecting qualitatively the results on the optimum strategy in the early stages of industrialization. See fn. 12 below.

In addition, we have the *nonnegative restriction* on sectoral capital and labor allocations (K_i, $L_i \geq 0$).

II

General Equilibrium under Nonspecialization[6]

To understand the structure of factor allocation under nonspecialization, it is useful to distinguish between the capital-labor ratio of the economy, k, and the aggregate capital-labor ratio of the industrial sectors, k'. Let the difference between the capital (labor) endowment and the quantity demanded by the primary sector under nonspecialization be $S_K(S_L)$ (i.e., "surplus" capital (labor)). Then

$$k' \equiv \frac{S_K}{S_L} = \frac{kL - \hat{K}_a}{L - \hat{L}_a} \tag{13}$$

In this expression, $\hat{K}_a$ and $\hat{L}_a$ will be constants. This is because together with $\hat{k}_i(i=b, c)$, and $\hat{r}$, $\hat{w}$ they are determined by marginal productivity conditions (7)–(8), (9)–(10), and they are thus independent of factor endowments and depend only on prices and technology which are assumed given. Thus we put $\hat{K}_a$ $K_a(p_a, q)$ and $\hat{L}_a = L_a(p_a, q)$.[7]

The allocation of surplus factors to the industrial sectors will now be determined as is usual in two sector models, with k' replacing k. Let us write $k_i(q)$ for $\hat{k}_i(i=b, c)$ and $k'(k, L)$ for k'. Then resource constraints (11)–(12) imply the following condition for nonspecialization, i.e., for $\hat{L}_b$, $\hat{L}_c > 0$ (provided S_K and S_L are both positive):

$$k_c(q) > k'(k, L) > k_b(q) \tag{14}$$

Condition (14) states that a necessary and sufficient condition for a positive output of both industrial goods is for the aggregate industrial capital-labor ratio to lie between the capital-labor ratios of the heavy-industry and light-industry sector. The $S_K = 0$ and $S_L = 0$ schedules are drawn in Figure 1; they intersect at $E[L_a(p_a, q), k_a(p_a, q) \equiv K_a(p_a, q)/L_a(p_a, q)]$. The area of (k, L) where S_K, $S_L > 0$ is the area to the right of $S_K = 0$ which lies above $S_L = 0$. The $k_c(q) = k'(k, L)$ schedule (which corresponds to $\hat{L}_b = 0$) and the $k_b(q) = k(k, L)$ schedule (which corresponds to $\hat{L}_c = 0$) are also drawn. Both intersect at E and are upward sloping since, from (13)

$$\frac{\partial k'}{\partial k} = \frac{L}{L - L_a(p_a, q)} > 0 \qquad (\text{for } S_L > 0)$$

$$\frac{\partial k'}{\partial L} = -\frac{L_a(p_a, q)}{[L - L_a(p_a, q)]^2}[k - k_a(p_a, q)] < 0^{8}$$

Condition (14) holds in the shaded area which lies between these two schedules, and this will therefore be the nonspecialization region. The next step is to determine the regions in (k, L) where only one industrial good should be produced in addition to the primary good—industrial specialization—and where no industrial good should be produced—agricultural specialization. We start with industrial specialization in, say, light industry. A necessary condition for this pattern to be optimum is for the marginal productivity conditions (holding with equality) of the light-industry and agricultural sectors to be consistent with the resource constraints for $L_b > 0$, $L_c = 0$ (we already know that L_a must always be positive). This is *feasibility*, a necessary condition for optimality. *Optimality* of light-industry specialization in addition requires the shadow prices of

[6] The circumflex identifies the variables of this phase of specialization.

[7] Thus the output of the primary sector and the production techniques of all sectors are constant under nonspecialization.

[8] Thus an increase in the size of the economy (i.e., a proportional increase in both capital and labor) will increase the share of light industry in total industrial output. This effect is similar to the effect of "growth acceleration" in my earlier article.

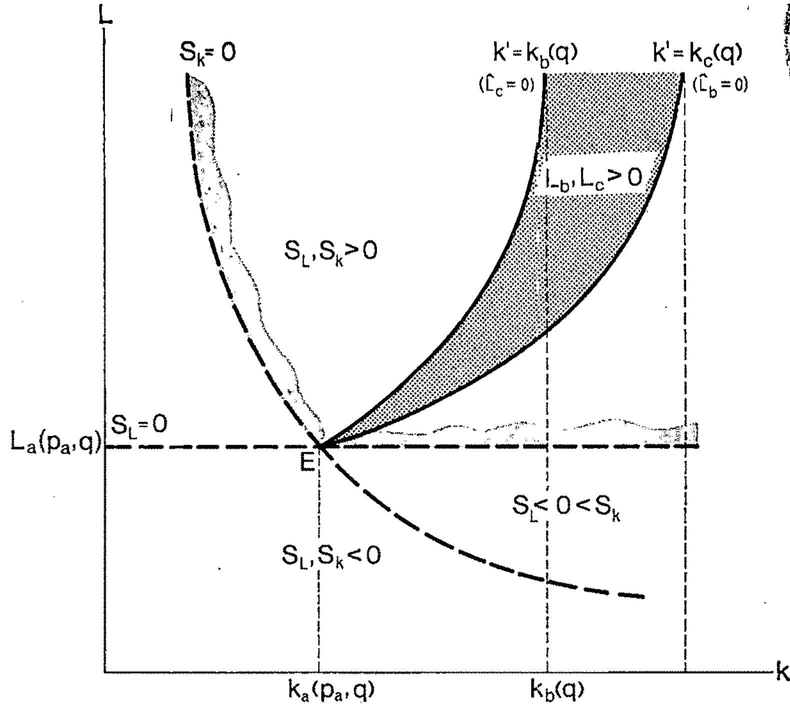

FIGURE 1

capital and labor in this phase of specialization to be equal to or greater than the marginal product of capital and labor in the nonproducing (heavy-industry) sector (at least one of these conditions must hold with strict inequality).

Feasibility of Light-Industry Specialization[9]

From marginal conditions (7), (8), (9), and (10) we obtain an implicit relationship between the sectoral capital-labor ratios in this phase, $\bar{k}_i$ and primary-sector labor L_a:

$$\bar{k}_i = \bar{k}_i(L_a) \qquad (i = a, b) \tag{15}$$

It follows from differentiation of the above marginal conditions that $\bar{k}_i'(L_i) < 0$, i.e., that the marginal conditions for light industry and agriculture imply an increase in primary-sector labor to be accompanied by a reduction in the capital-labor ratios of both sectors.[10] This is shown in Figure 2A.

To obtain the actual labor allocations we introduce (15) into resource constraints (11) and (12) for $L_c = 0$:

$$\frac{L_a}{L} = \frac{\bar{k}_b(L_a) - k}{\bar{k}_b(L_a) - \bar{k}_a(L_a)} \tag{16}$$

This equation determines the actual labor allocation to the primary sector as a function of (k, L). We will denote it by $\bar{L}_a(k, L)$. Introducing this value into (15), we obtain the sectoral capital-labor ratios.

Feasibility of light-industry specializa-

[9] The variables of this phase of specialization are barred.

[10] The actual expression for $\bar{k}_a(L_a)$ is:

$$\bar{k}_a(L_a) = -\frac{\bar{k}_a}{L} \cdot \frac{\frac{d}{dL_a}(F_k^a) + \frac{d}{dL_a}(F_L^a)}{k_b F_{KK}^a + F_{KL}^a} < 0$$

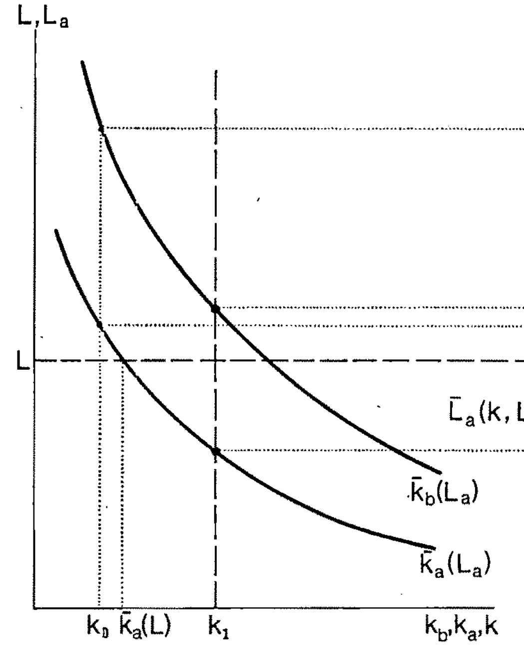

FIGURE 2A

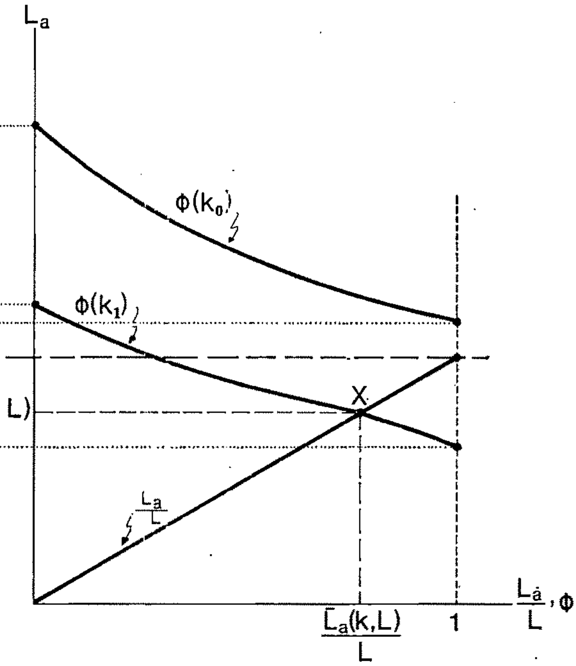

FIGURE 2B

tion means

$$(17) \qquad \bar{L}_a(k, L) < L.$$

We will show that a necessary and sufficient condition is $k > \bar{k}_a(L)$. Suppose that $k = k_0 < \bar{k}_a(L)$. It is clear in this case from Figure 2A that L_a/L (the left-hand side of (16)) less than unity implies that the right-hand side of (16)—which we will denote by ϕ—is greater than unity. Thus, light-industry specialization is not feasible when $k < \bar{k}_a(L)$. On the other hand, when $k > \bar{k}_a(L)$ there will necessarily be a solution to (16) which satisfies (17). To show this we represent both L_a/L and ϕ as functions of L_a in Figure 2B. At the level of L_a which makes $\bar{k}_b(L_a)$ equal to the capital-labor ratio of the economy, say k_1, we have $\phi = 0$. On the other hand, when $k_1 = \bar{k}_a(L_a)$ we have $\phi = 1$. At intermediate levels of L_a, ϕ will necessarily be a declining function of L_a.

The figure shows clearly that when $k = k_1 > \bar{k}_a(L)$, the ϕ and L_a/L schedules intersect at a level $\bar{L}_a(k, L) > L$ (point X). On the other hand, there is no such solution when $k = k_0 < \bar{k}_a(L)$. Thus in the (k, L) space, light-industry specialization is feasible at and only at points above and to the right of the $\bar{k}_a(L)$ schedule.

Similarly for feasibility of heavy-industry specialization.[11] We obtain a $\tilde{k}_a(L_a)$ schedule from the marginal productivity conditions of the agricultural and heavy-industry sectors. Then feasibility of this pattern of specialization implies $k > \tilde{k}_a(L)$. Will the $\bar{k}_a(L)$ and $\tilde{k}_a(L)$ schedules intersect? The answer is yes and precisely at point E. This is so because the marginal productivity conditions of *all three* sectors hold for $L_a = L$, $L_b = L_c = 0$ at both E and at the intersection of $\tilde{k}_a(L_a)$ and $\bar{k}_a(L)$. Moreover, as we have seen, this can only hold at one point. In addition, since $k_c > k_b$, it is easily shown that $\tilde{k}_a'(L)$

[11] The tilde identifies the variables of this phase.

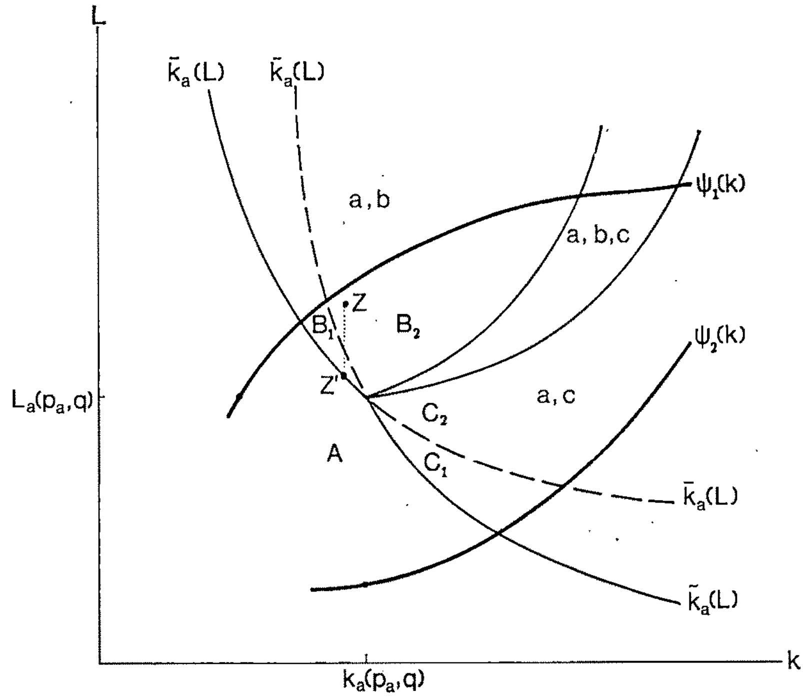

FIGURE 3

$<\bar{k}_a'(L)<0$. Hence, the $\hat{k}_a'(L)$ and $\bar{k}_a'(L)$ schedules look as in Figure 3.

Optimality of Industrial Specialization

There are five regions in the (k, L) space: A, B_1, B_2, C_1, and C_2 apart from the non-specialization region (see Figure 3). We have to find the optimum specialization patterns in each of them.

PROPOSITION 1: *Agricultural specialization is optimum if, and only if, the economy lies in A.*

PROOF:

If the economy is in A the only feasible pattern of specialization is agricultural specialization. Hence this is also the optimum pattern. In the Appendix we prove that agricultural specialization is not optimum at any point outside A (though, it is, of course, feasible).

PROPOSITION 2: *Light-industry specialization is optimum in B_1 and B_2 and heavy-industry specialization is optimum in C_1 and C_2.*

PROOF:

In B_1 the only feasible patterns are agricultural specialization and light-industry specialization. From Proposition 1, agricultural specialization is not optimum. This leaves light-industry specialization as the optimum pattern. Similarly, in C_1 the optimum is heavy-industry specialization. In addition there are a priori indications that light-industry specialization is optimum in B_2 and heavy-industry specialization in C_2. This is so because in B_2 resource constraints imply $\hat{L}_c<0$ while in C_2 they imply $\hat{L}_b<0$. A rigorous proof is given in the Appendix.

The optimum patterns of specialization

in the (L, K) space are shown in Figure 3.[12]

III

The main resource-allocation implication of the model is that there is a minimum capital-labor ratio for heavy industry and a minimum scale (or labor force) for light industry. These are $k_a(p_a, q)$ and $L_a(p_a, q)$, respectively, the capital-labor ratio of and the labor allocation to agriculture under nonspecialization.

The minimum capital-labor ratio required for heavy industry is likely to diminish when the returns to scale of the primary sector increase. Thus, when no agriculture is possible, an extreme case where there are no natural resources at all, this three-sector model with agriculture reduces to the standard two-sector model where $k_b(q) > k_a(p_a, q)$ is the minimum capital-intensity level for the development of heavy industry. Moreover, if we consider the class of agricultural production functions which are homogeneous of degree less than one, $y_a = L_a^r f_a(k_a)(0 > r > 1)$. We find, after substituting into the agricultural marginal productivity conditions, that

$$\frac{dk_a(p_a, q)}{dr} < 0, \qquad \frac{dL_a(p_a, q)}{dr} > 0$$

That is, an increase in the degree of homogeneity of the agricultural production function reduces the minimum capital-labor ratio required for the establishment of heavy industry (and increases the minimum scale required for the establishment of light industry).

The minimum scale required for light industry is part of a general differential scale effect favorable to this sector and relatively unfavorable to heavy industry. This is clearly shown within the nonspecialization sector. It is also reflected in the possible shifts from one phase to another induced by changes in scale. Consider, for example, an economy with $k_a(p_a, q) < k < k_b(q)$. At a relatively small scale, this economy should be in the phase of heavy-industry specialization. At a somewhat larger scale it shifts to nonspecialization and at a still larger scale to light-industry specialization.

PROPOSITION 3: *For the class of factor accumulation paths where population growth is associated with capital deepening, industrialization should start with light (heavy) industry if the minimum scale required for the development of light industry is attained before the minimum capital-labor ratio required for the development of heavy industry (if the minimum capital-labor ratio for the development of heavy industry is attained before the minimum scale for the development of light industry).*

The proof can be seen by observing paths $L = \psi_1(k)$ and $L = \psi_2(k)$ of Figure 3. This and the previous discussion imply:

PROPOSITION 4: *The possibility of developing heavy industry in the early stages of industrialization is greater (a) the greater the rate of capital accumulation relative to the rate of population growth; (b) the greater the initial capital stock and the lower the initial labor force; and (c) the greater (other things equal) the efficiency of the agricultural sector.*

[12] When (5) does not hold, i.e., if

$$(5') \qquad 0 < \lim_{\substack{L_a \to 0 \\ k_a > 0}} F_L^a(k_a L_a, L_a) = M < \infty$$

it may be optimal—for some factor endowments—to produce industrial goods only, provided the scale of the economy is sufficiently high. In such a case, regions in which there is no agriculture would also have to be described in Figure 3. However, the neoclassical technology will always ensure that between the region of agricultural specialization and the region with no agriculture, we will always have some region with both industry and agriculture. Hence, the same alternative transistions between agriculture and industry which are implicit in Figure 3 (and which are discussed in the next section) also hold when (5′) holds.

The commonly held view that an optimum industrialization strategy must *necessarily* start with the development of light industries is seriously put to question. This and my 1971 paper show that it is theoretically possible, both for a small economy and for a medium-sized one, for the optimum strategy to involve the development of heavy industry in the initial stages of industrialization. However, without knowledge of the orders of magnitude of the parameters of the model we cannot say at this stage whether this possibility is or is not a realistic one for today's developing countries.

The crucial condition for this variety of industrialization strategies seems to be the existence of at least one sector with non-constant returns to scale. It is interesting that this need not be an industrial sector. Moreover, the results obtained do not depend on assumptions about the nature of the agricultural production function (in addition of decreasing returns to scale) or on the assumption of perfect intersectoral mobility of capital, or on differential external effects. Finally, the optimality of developing heavy industries at the early stages of industrialization does not hinge on the assumption of a closed (or semi-closed) economy but is, under certain circumstances, derived from the principle of comparative costs itself.

APPENDIX

PROPOSITION (1′): *Agricultural specialization is never optimum at points outside region A.*[13]

PROOF:

We have to prove that at least one optimality condition for agricultural specialization is violated at points to the left of E and above $\bar{k}_a(L)$ and to the right of E and above $\bar{k}_a(L)$. Take point Z of Figure 3. We first show that conditions (1) and (2) cannot hold simultaneously.

$$(1) \qquad \overset{\circ}{w}{}^{z} = p_a F_L^a(kL^z, L^z) \geqq q \frac{\partial F^b}{\partial L_b}(\overset{z}{k}_b)$$

$$(2) \qquad \overset{\circ}{r}{}^{z} = p_a F_K^a(kL^z, L^z) \geqq q \frac{\partial F^b}{\partial K_b}(\overset{z}{k}_b)$$

Suppose (2) holds. We then prove that (1) cannot hold. Consider point Z' on $\bar{k}_a(L)$ just below Z, i.e., $k^{z'} = k^z$; $L^{z'} < L^z$. Then,

$$(3) \qquad \overset{\circ}{r}{}^{z'} > \overset{\circ}{r}{}^{z}; \qquad \overset{\circ}{w}{}^{z'} > \overset{\circ}{w}{}^{z}$$

since reductions in scale increase the marginal products of both capital and labor in agriculture. Moreover, as Z' lies on $\bar{k}_a(L)$ we have (for $L_b = 0$)

$$\overset{\circ}{r}{}^{z'} = p_a F_K^a(kL^{z'}, L^{z'}) = q \frac{\partial F^b}{\partial K_b}(\overset{z'}{k}_b)$$

This relation together with (3) and (2) (which we assumed holds) implies

$$\frac{\partial F^b}{\partial K_b}(\overset{z'}{k}_b) > \frac{\partial F^b}{\partial K_b}(\overset{z}{k}_b) \text{ and hence } \overset{z}{k}_b > \overset{z'}{k}_b$$

Therefore

$$q \frac{\partial F^b}{\partial L_b}(\overset{z}{k}_b) > q \frac{\partial F^b}{\partial L_b}(\overset{z'}{k}_b) = \overset{\circ}{w}{}^{z'}$$

which, given (3), violates (1). Similarly, it can easily be proved that when (1) holds, (2) cannot hold.

PROPOSITION (2′): *In C_2 the optimum phase is heavy-industry specialization while in B_2 the optimum is light-industry specialization.*

PROOF:

We show that at points in C_2 the following optimality conditions for light-industry specialization cannot hold simultaneously:

[13] Under agricultural specialization the variables will be capped by °. Thus, $\overset{\circ}{k}_a = k$ and $\overset{\circ}{L}_a = L$. When the variables corresponding to a particular point in (k, L) are referred to, a superscript with the letter denoting the point will be added.

$$(4) \qquad \bar{r} = q \frac{\partial F^b}{\partial K_b} (\bar{k}_b) \geq \frac{\partial F^c}{\partial K_c} (k_c)$$

$$(5) \qquad \bar{w} = q \frac{\partial F^b}{\partial L_b} (\bar{k}_b) \geq \frac{\partial F^c}{\partial L_c} (k_c)$$

We start by assuming that (4) holds with equality in C_2, thus defining for each point a particular value of k_c which we call $\bar{k}_c$,

$$(4') \qquad \bar{r} = q \frac{\partial F_b}{\partial K_b} (\bar{k}_b) = \frac{\partial F^c}{\partial K_c} (\bar{k}_c)$$

We now show that given (4′), (5) cannot hold in C_2. Note that the C_2 region is bounded by the $\bar{k}_a(L)$ and $k_c(q)=k'$ schedules. Along $\bar{k}_a(L)$ (to the right of E) the optimum policy is heavy-industry specialization, which, given (4′), implies violation of (5). Along $k_c(q)=k'$, on the other hand, the optimum also involves heavy-industry specialization, although it is a border case where (5) holds with equality. Therefore, for (5) to hold with strict inequality at some point in C_2 given (4′), it must hold with equality at some other point in C_2, since all the functions in (5) are continuous. But, given (4′), (5) can only hold with equality in the non-specialization region, since in any other region, the nonnegativity restrictions would be violated. Therefore, given (4′), equation (5) cannot hold in C_2, i.e.,

$$(6) \qquad \bar{w} = q \frac{\partial F^b}{\partial L_b} (\bar{k}_b) < \frac{\partial F^c}{\partial L_c} (\bar{k}_c)$$

Suppose now that (4) holds with strict inequality. Then $k_c > \bar{k}_c$ and

$$\frac{\partial F^c}{\partial L_c} (\bar{k}_c) < \frac{\partial F^c}{\partial L_c} (k_c)$$

Together with (6), this violates (5). We conclude that heavy-industry specialization is optimum in C_2. An analogous analysis would prove that light-industry specialization is optimum in region B_2.

The Informational Efficiency of Monetary Exchange

By JOSEPH M. OSTROY*

The gains from exchange may be extended if individuals are not required at each trade to balance the value of purchases and sales. But self-interest, the motive force of trade, does not move individuals to realize these gains. Suppose that X has an excess demand for ten apples and an excess supply of ten oranges. It may be efficient for X to receive the ten apples from Y, who has an excess supply, and later give his ten oranges to Z, who has an excess demand. In the actual execution, what is to prevent X from asking for eleven apples from Y, justifying his claim by saying he will supply an equal number of oranges, or give up only nine oranges to Z, saying that he took only nine apples? The purpose of this paper is to show that the essential property of money is to discourage the making of such inconsistent claims without also discouraging efficient patterns of trade.

This is "old stuff"; but it cannot be incorporated into the standard theory of value.[1] To illustrate, consider a paradox contained in Robert Clower's (1967) proposal to introduce money into the standard theory. His suggestion was to add to the existing budget constraint the injunction that current purchases be financed by sale of money only, not by current supplies of other commodities. This modification contradicts the belief that the introduction of money improves the allocation of resources. Because it is an additional constraint, it is at best not binding; and if binding, it will narrow the set of permissible exchanges compared to its barter counterpart. Clower's constraint makes no sense in the Walrasian model of exchange, but for a perfectly sensible reason. It does no good to append what is a trading constraint to a model which ignores trade.

In the standard theory, equilibrium is said to exist when (W) the sum of individual excess demands is zero for each commodity. What (W) defines is a Walrasian equilibrium of prices. Nevertheless, from the individuals' points of view, they are in disequilibrium as long as we do not have (A) all individual excess demands are zero for each commodity.

Should the economy reach the state defined by (W), will it then go to (A)? Interpretations of the standard theory say that the Walrasian auctioneer, after announcing equilibrium prices, expedites demands and supplies. If there is one theme which distinguishes the present treatment from the standard theory, it is that exchange is a do-it-yourself affair. Individuals will not exchange with "the market"; they will exchange with each other. This elementary logistical consideration is the basis upon which I shall construct an argument for monetary exchange.[2]

* Assistant professor of economics, University of California, Los Angeles. I have benefited from discussions with Ronald Britto, Jack Hirschleifer, Ben Klein, Axel Leijonhufvud, Louis Makowski, Richard Sweeney, Earl Thompson, and Joseph Wharton. Bryan Ellickson, Peter Howitt, and Ross Starr made many improvements in the formulation and presentation. My introduction to the topic came through the research of Robert Clower whose continued advice and encouragement were invaluable.

[1] By this phrase I mean the model of general equilibrium first proposed by Walras and recast into its definitive mathematical form by such contributors as Arrow and Debreu.

[2] Recently, formal notice has been taken of the fact that the valuable exchange services rendered by the

I. Summary

I shall assume that trade occurs between pairs of individuals so that the advantages of multilateral exchange must be obtained through a sequence of bilateral trades. During a unit interval of time, an individual meets with only one other so that during the interval an individual's trades are limited by his own and his trading partner's current endowments. When one pair meets, other pairs are also making contact, so that exchange occurs as a sequence of *simultaneous* bilateral trades.[3]

In the comparison of money and barter trading arrangements, no explicit account is taken of the physical or psychic costs of exchange. The single criterion is the number of periods it takes to accomplish the task of going from (W) to (A). Any decrease in the number is good and any increase is bad. Obviously a crude picture of the costs of exchange, it may be tolerated because the object is only an exposition of the role of money, not a general theory of trade.[4]

In the analysis of the problem of going from (W) to (A), I shall focus on the following three properties of trading sequences: (i) their technical feasibility, (ii) their informational feasibility, and (iii) their equilibrium properties, or what might be called their "behavioral feasibility." Property (i) defines the restrictions on a sequence of exchanges imposed by the fact that trade occurs between pairs. Property (ii) requires (i) and the restriction that a pair cannot base its trading decision on information available only to other pairs. For example, a pair cannot make its decisions depend on the full details of excess demands among all other pairs. Property (iii) requires (ii) and the restriction that each individual have no incentive to depart from the sequence. In a barter economy, if trades leading from (W) to (A) do not satisfy bilateral balance (BB)—where the value of purchases and sales are equated at each bilateral encounter—those trades will not form an equilibrium sequence.

We shall see that those trades which are technically and/or informationally feasible and which also minimize the number of periods in going from (W) to (A) will not satisfy BB. Imposition of BB does not preclude equilibrium in the sense of (A); it only means that it will take longer. But this time is not well spent because there is no technical or informational constraint underlying it. Additional time is required because individuals do not feel constrained to balance their budgets over a sequence of trades if they are not so compelled at each

auctioneer are costly to provide. Much of the motivation for these studies has been a desire to fit monetary exchange into the standard theory. We may learn from some of them that costly exchange can be introduced without giving up the assumption that exchange is coordinated by a central agency—an auctioneer who charges for his services. See Frank Hahn (1971), Mordecai Kurz, Jürg Niehans (1971), K. C. Sontheimer and N. Wallace. According to the present treatment, however, it is only when the exchange process is decentralized that the role of money can be understood. See Clower (1971). We may learn from Niehans (1969) that even when exchange is restricted to pairs it need not be completely decentralized. The selection of a least cost bilateral trading network can be made by a central planner who solves a complicated programming problem. A similar difficulty occurs in Starr (1970) where individuals choose optimal *sets* of bilateral transactions but require a central agency to hook them together. Roy Radner and Karl Brunner and Allan Meltzer have approached monetary exchange as a reflection of imperfect information. Radner has suggested that money might arise from the unpredictability of future spot prices and Brunner and Meltzer have indicated that money arises because of the need for a commonly recognizable asset. I shall discuss these points in Section IV. The present treatment is related to the work of Hicks, Starr (1972), and E. C. H. Veendorp.

[3] It is this simultaneity—while one pair is exchanging other pairs are not standing still—which contributes to the informational demands on trade.

[4] It would have been possible to formulate a model in which the costs of exchange varied with the amounts of commodities and the number of individuals with whom one traded per unit time. Ignoring the resulting complexities, the outcome must concede that not everyone exchanges everything at once if it is to gain insight into monetary exchange.

trade. Any device which would encourage such constraint could be substituted for the added time. Money is such a device.

I shall assume throughout that individuals know equilibrium exchange rates. Because we are accustomed to thinking of equilibrium in the sense of (W), this assumption may appear to be disquietingly strong. In general, it is; but *not* for the purposes of understanding monetary exchange. The line of reasoning adopted here permits me to assert that if we cannot find a role for money when equilibrium prices are known, we shall not find one when they are unknown. There can hardly be a speculative demand for the medium of exchange without a transactions demand and this transactions demand does not depend on price uncertainty.

II. A Model of a Trading Economy

There are three components of the model: (i) the set of possible tastes and endowments and their corresponding competitive equilibrium allocations; (ii) the logistical description of the trading arrangement; and (iii) the pattern of information describing what individuals know and do not know at each trading opportunity.

A Family of Exchange Economies

Individual i is initially endowed with a nonnegative quantity w_{ic} of commodity $c=1, \ldots, m$. The complete list of his initial endowments is the m-vector $w_i=(w_{i1}, \ldots, w_{im})$. If i, whose tastes are represented by $u_i(\cdot)$, were asked to exchange his initial endowment for any other (m-vector) x_i satisfying the constraint $p\cdot x_i=p\cdot w_i$, where $p=(p_1, \ldots, p_m)$ is the vector of prices, let his answer be the bundle $a_i=(a_{i1}, \ldots, a_{im})$, $a_{ic}\geq 0$, $c=1, \ldots, m$ and

$$(1) \qquad u_i(a_i) = \max u_i(x_i), \quad p\cdot a_i = p\cdot x_i = p\cdot w_i{}^{5}$$

[5] $p\cdot w_i\equiv\Sigma_c p_c w_{ic}$ is the dot product of p and w_i.

At prices p, let i be described by the pair of vectors (a_i, w_i) and let the collection of individuals $i=1, \ldots, n$ be described by the pair of matrices (A, W), where a_i and w_i are the ith rows of the nxm matrices A and W, respectively. The pair (A, W) forms a competitive equilibrium (CE) if the aggregate demand for each commodity is equal to the aggregate supply,

$$(2) \qquad \sum_i a_{ic} = \sum_i w_{ic}, \qquad c = 1, \ldots, m$$

The matrix A *is the CE allocation* for the CE price vector p and matrix of initial endowments W. The problem of going from equilibrium in the sense of (W) to equilibrium in the sense of (A) is now reduced to the problem of going from the matrix W to the matrix A.

I shall deal only with collections of individuals described by nonnegative matrices (A, W) satisfying

$$(3) \qquad n = m$$

and

$$(4) \qquad \sum_i a_{ic} = \sum_c a_{ic} = \sum_i w_{ic} = \sum_c w_{ic} = 1$$

The set of all such pairs of nxn matrices whose row and column sums are unity, call $\mathcal{U}$. If (4) is to satisfy (1) for every member of $\mathcal{U}$, any $p=(r, r, \ldots, r)$, $r>0$, must be a CE price vector. This will mean that if i knows he is in an economy belonging to $\mathcal{U}$, he knows equilibrium exchange rates.

In the space of all possible economies, the set $\mathcal{U}$ occupies only a small corner. I choose to deal with it because $\mathcal{U}$ exhibits the salient features of the general case. The assumption in (3) that the number of commodities is equal to the number of individuals is, strictly speaking, not essential to our results and can be shown to follow a fortiori if $m>n$. However, the trading ar-

rangement I shall postulate allows each individual's trading opportunities to increase with the size of the population so that as n/m increases the logistical problems of exchange disappear.

The assumption that individual endowments are of the same size ($\sum_c w_{ic}=1$, $i=1, \ldots, n$) is significant only insofar as it makes clear that there is no individual whose initial endowment is, for *all* $(A, W) \in \mathcal{U}$, large enough for him to act as a central distributor supplying everyone else's excess demands.[6] The set $\mathcal{U}$ exhibits a similar feature with respect to the insufficiency of endowments to permit a medium of exchange.

About the origin and use of money, Adam Smith said:

> In order to avoid the inconvenience of such situations, every prudent man in every period of society, after the first establishment of the division of labour, must naturally have endeavoured to manage his affairs in such a manner, as to have at all times by him besides the peculiar produce of his own industry, a certain quantity of some one commodity or other, such as he imagined few people would be likely to refuse in exchange for the produce of their industry. [p. 22]

The purpose of this paper is to isolate the function of a medium of exchange and I shall proceed by analyzing the difficulties when one does not have "a certain quantity of some one commodity." There is no commodity whose initial value is, for *all* $(A, W) \in \mathcal{U}$, a significant fraction of the value of each individual's planned purchases.[7] This will allow me to bring out more clearly that the essential feature of monetary exchange has its origin in the trading arrangement and not in the nature of the money commodity.[8]

The first result, which serves as an introduction to the problem, is

PROPOSITION 1: *For almost all $(A, W) \in \mathcal{U}$, if the collection of n individuals is divided into any two groups consisting of k and $n-k$ individuals, $1 \leq k \leq n-1$, who cannot trade with each other, the CE allocation cannot be obtained.*[9]

If $n>2$, there is little hope of finding a double coincidence of wants. In fact, everyone will have to depend on everyone else if the *CE* allocation is to be realized.

How Traders Meet

I shall assume that the sequence of pairwise meetings is parametric rather than a subject for choice. From his point of view, each individual seems to collide every so often with someone else.

Let $\pi = \{\pi^t\}$, $t=1, \ldots, \tau$ be a sequence of permutations of the integers $i=1, \ldots, n$ such that for all i and t,

$$\pi^t(i) = j \tag{5}$$

if and only if $\pi^t(j) = i$

The permutation π^t determines who meets whom at t; i.e., $\pi^t(i) = j$ means i and j are trading partners at t. The final period, after which all trading ceases, is $t=\tau$.

Let $\{W^t\}$, $t=1, \ldots, \tau+1$, τ be a sequence of matrices with nonnegative elements where $W^t = (w^t_{ic})$ is the matrix of endowments at the beginning of t. Suppose $\pi = \{\pi^t\}$ describes the sequence of meetings; then $\{W^t\}$ *is technically feasible for* π, if for all i and t and $\pi^t(i) = j$,

$$\overset{t+1}{w_i} + \overset{t+1}{w_j} = \overset{t}{w_i} + \overset{t}{w_j} \tag{6}$$

[6] For example, individual j could be a central distributor for (A, W) if $w_{jc} > \delta$, $c=1, \ldots, m$, and if max $|a_{ic} - w_{ic}|$ over all c and $i \neq j$ were less than δ/n.

[7] For example, commodity d could be used as a medium of exchange for (A, W) if $w_{id} > \delta$, $i=1, \ldots, n$, and if max $|a_{ic} - w_{ic}|$ over all i and $c \neq d$ were less than δ/m.

[8] These qualifications as well as their consequences are more fully discussed in Ostroy and Starr.

[9] PROOF: Suppose the contrary; then it would require that for some subset, T, consisting of fewer than n individuals, $\Sigma_{i \in T}(a_i - w_i) = 0$. This defines a less than full dimensional class of economies in $\mathcal{U}$.

This says that an individual can add to his current endowment only by subtracting from the current endowment of his current trading partner and that commodity totals are not changed in the process of trade, just redistributed.

If the sequence $\{W^t\}$ *also* satisfies

$$(7) \qquad p\cdot(w_i^{t+1} - w_i^{t}) = 0$$

for all i and t, where p is the *CE* price vector, then *bilateral balance* (*BB*) obtains. At every bilateral encounter, the value of what is given up is equal to the value of what is received. Clearly, *BB restricts the set of trades beyond the demands of technical feasibility.*

Let us agree to say that the *CE allocation is technically feasible for* π if, for *all* $(A, W)\in\mathfrak{U}$, there exists a sequence $\{W^t\}$, technically feasible for π, with $W^1=W$ and $W^{\tau+1}=A$. This means that the sequence π is not biased; it permits all possible *CE* configurations to be realized. Denote by Π_τ the set of all such π of length τ.

What is the minimum value of τ for which the *CE* allocation is technically feasible? Proposition 1 tells us that everyone must be "connected" to everyone else but this connection need not be direct since (6) permits indirect or middleman trade.

PROPOSITION 2: *If* $n=2^k$, $k=1, 2, \ldots,$ *the minimum number of periods for which the CE allocation is technically feasible is*[10]

$$\tau = k(\tau = log_2\, n)$$

To demonstrate, note that it is true for $k=1$, and assume it is true for $k=q$. This means that any group consisting of 2^q individuals can be connected in q periods so that two groups each consisting of 2^q individuals can be connected in period $q+1$ if every member of the one group is assigned to a member of the other. Since $2\cdot 2^q=2^{q+1}$, Proposition 2 is proved.

Call such a π which satisfies Proposition 2 an *indirect trading sequence* and a trading economy which makes use of it an *indirect exchange model.* It should be pointed out that

PROPOSITION 3: *If trades must satisfy BB, the CE allocation is not technically feasible for the indirect exchange model.*[11]

Suppose every individual is permitted to meet every other directly. Obviously, the *CE* allocation will be technically feasible. This will require $n(n-1)/2$ bilateral meetings and assuming n is even, will take, at a minimum, $\tau=n-1$ periods. Call such a sequence which allows everyone to meet everyone else in a minimum number of periods a *direct exchange sequence* and a trading economy which makes use of it a *direct exchange model.* An interesting feature of this model is

PROPOSITION 4: *If trades must satisfy BB, the CE allocation is technically feasible for the direct exchange model.*[12]

Propositions 3 and 4 say that it takes longer to reach the *CE* allocation if *BB* is imposed. Alternatively, the temporal advantages of the indirect exchange model are incompatible with *BB*. This will not, by itself, offer a basis for monetary exchange. Other considerations intrude.

How Trades Are Made

I shall make a distinction between (a)

[10] The following was obtained in correspondence with Lloyd Shapley: To complete the solution to minimizing the number of time periods for $n\neq 2^k$, let m be the largest integral power of two such that $m=2^k<n$. Then, $\tau=(log_2 m)+1$ if n is even and $n\neq 2^k$ and $\tau=(log_2 m)+2$ if n is odd.

[11] Proposition 3 holds for all $n\geq 4$, the smallest number for which the advantages of indirect trade appear. See the *Remark* following Proposition 5 for a demonstration in the case $n=4$.

[12] Proofs of Proposition 4 are in Ostroy and Starr, and G. Bradley.

the decision a pair of traders make based on the information they reveal to each other and (b) the decision as to what information to reveal. It will be assumed that (a) is taken out of the hands of the pair and given to a fictional third party, a broker, who makes the trading decision solely on the basis of what each member of the pair tells him. We may suppose that the broker uses his unlimited ingenuity and computational capacity to help the pair reach their *CE* allocations. His only constraint is that he knows no more than what the pair tells him. Until Section IV, the decision (b) will be ignored by assuming that there is no distinction between what individuals know and what they reveal.[13]

At the beginning of period t, those features of the economy which cannot be changed constitute the state of the economy. They are the initial configuration of tastes and endowments, the order in which pairs will meet, and the trades which have been made up to t. Denote a typical state by $\hat{S}^t=(\hat{A}, \hat{W}^1, \ldots, \hat{W}^t; \hat{\pi})$. The set of all possible states at t is

$$(8) \quad \mathcal{S}^t = \{\hat{S}^t: (A, \hat{W}^1) \in \mathcal{U} \text{ and } \{\hat{W}^k\}, \; k = 1, \ldots, t \text{ is technically feasible for some } \hat{\pi} \in \Pi_\tau\}$$

Suppose the actual state is $S^t=(A, W^1, \ldots, W^t; \pi)$. Let $I_i^t(S^t)$ be the information i has at t about the actual state. It will be assumed throughout that

$$(9) \quad I_i^t(S^t) = \{\hat{S}^t \in \mathcal{S}^t: \hat{a}_i = a_i, \hat{w}_i^k = w_i^k, \; \hat{\pi}^k(i) = \pi^k(i), k = 1, \ldots, t\}$$

If you were to ask i what he knows about the state of the economy, according to (9) he would say: "I have no idea. All I know is that it belongs to the set of possible states, and I can therefore tell you what *CE* prices are, and what I would want if I had to balance my budget at those prices, and that I have made certain trades as indicated by $\{w_i^k\}$, $k=1, \ldots, t-1$, leading to my current position w_i^t."[14]

Each member of a pair of trading partners tells what he knows to the broker who then decides what trades they should make. The different trading pairs have different brokers who cannot communicate so the situation is much the same as if the pair themselves decided what to trade.

As a formalization of this story, let $\rho_i^t(I_1^t(S^t), \ldots, I_n^t(S^t))=w_i^{t+1}$, $i=1, \ldots, n$, be a trading rule, changing w_i^t into w_i^{t+1}, which depends on the actual state of the economy and what individuals know about it. I shall say that $\rho=\{\rho_i^t\}$ *is an informationally feasible trading rule* if for all i and t, and $\pi^t(i)=j$,

$$(10) \quad \rho_i^t + \rho_j^t = w_i^t + w_j^t$$

and, for all $\hat{S}^t \in I_i^t(S^t) \cap I_j^t(S^t)$,

$$(11) \quad \rho_i^t(I_1^t(\hat{S}^t), \ldots, I_n^t(\hat{S}^t)) = \rho_i^t(I_1^t(S^t), \ldots, I_n^t(S^t))$$

Condition (10) says the rule must be technically feasible. If the pair (i, j) were to share their information they could determine that the actual state was in the set $I_i^t \cap I_j^t$ and nothing more. Condition (11) says that the trading decision must respect this ignorance, which is to say that each pair's trading decision cannot be made contingent on the tastes and trading histories of other pairs.[15]

[13] Getting individuals to reveal what they know, for example, their tastes, has been recognized as the principal difficulty in allocating collective goods (see Paul Samuelson). We shall see that there are similar strategic issues in a barter economy.

[14] This is the game-theoretic method for describing imperfect information. J. C. Harsanyi has shown how this may be applied to the case of players in a game who do not know each others' payoffs. The treatment above was developed independently in Ostroy (1970).

[15] The less one knows the smaller is his set of possible strategies. See Radner for a restriction similar to (11).

Once a trading rule is selected, the course of the economy is uniquely determined by its initial state. Given $S^1=(A, W^1; \pi)$, (9) determines $\{I_i^1(S^1)\}$, the input into the trading rule $\{\rho_i^1\}$, which determines W^2 and therefore $S^2=(A, W^1, W^2; \pi), \ldots$, etc. To summarize this recursive relation, let us say that if the initial state is $(A, W; \pi)$ and the trading rule is ρ, the end result is $g_i[\rho|(A, W; \pi)] = w_i^{\tau+1}$, $i=1, \ldots, n$.

Now, *the CE allocation is informationally feasible* if there exists an informationally feasible trading rule $\rho=\{\rho_i^t\}$ such that for *all* $(A, W)\in\mathfrak{U}$ and $\pi\in\Pi_\tau$, $g_i[\rho|(A, W; \pi)] = a_i$, $i=1, \ldots, n$. To illustrate this definition, consider the first period trading decision for any pair (i, j). If the CE allocation is informationally feasible, their broker has a sure-fire method for putting them on a path leading to their CE allocation no matter what the values of a_k and w_k, $k\neq i, j$.

III. Informational Aspects of Trade

In this section, the consequences of informational feasibility are explored. First, we have

PROPOSITION 5: *The CE allocation is not informationally feasible in the indirect exchange model.*

To demonstrate, take $n=4$. Let the trading partners be assigned as follows: individual 1's trading partners in the first and second periods are $\pi^1(1)=2$ and $\pi^2(1)=3$ while 4 is the partner of 3 in the first period and of 2 in the second $-\pi^1(3) = \pi^2(2)=4$. It is readily verified that this sequence allows each individual to trade directly or indirectly with everyone else. From Proposition 2, this is the minimum number of periods since $\tau=log_2 4=2$. Assume that initial endowments are given by the identity matrix; i.e., $w_{ic}=1$, if $i=c$, and $w_{ic}=0$ if $i\neq c$, where $i, c=1, 2, 3, 4$. This will simplify the demonstration, but it is not essential.

To go from W to A it is necessary that the exchange between individuals 1 and 2 be such that 1 begin the second period with $w_1^2=(w_{11}^2, w_{12}^2, w_{13}^2, w_{14}^2)$ where

$$(12) \quad w_{1c}^2 = \begin{cases} 1-(a_{2c}+a_{4c}), & \text{if } c=1 \\ (a_{1c}+a_{3c}), & \text{if } c=2 \\ 0, & \text{otherwise} \end{cases}$$

Individuals 1 and 2 do not know the tastes of 3 and 4, given by the vectors a_3 and a_4. According to (11), this means that for all possible values of a_3 and a_4, 1 and 2 must make the same trade. Now, whatever trade they make, they will have made the right decision for at most one pair (a_3, a_4) and will have made the wrong decision in all other cases. Therefore, the CE allocation is not informationally feasible.

Remark. The rule (12) is compatible with BB only if the configuration of tastes satisfies $a_{21}+a_{41}=a_{12}+a_{32}$; i.e., almost never.

I have assumed that individuals know only equilibrium prices and their own tastes and endowments. They do not know each other's excess demands and trading decisions are bound by this ignorance. But, to take advantage of indirect exchange, individuals must act as middlemen passing excess supplies in just the right sequence of intermediary trading to the final demander. What is the right sequence depends on the entire configuration of excess demands as well as on the order in which all pairs will meet. Proposition 5 brings out an obvious and basic point: *the informational requirements for indirect trade go beyond a knowledge of prices.*

Of course, the restrictions imposed on $\{I_i^t\}$ are rather harsh. I have taken the information available to an individual in the standard theory where he does not have to do his own trading and inquired as

to its sufficiency where he does. From here, it would be possible to go on to find the minimum information compatible with the result that the *CE* allocation is informationally feasible in the indirect exchange model. It has already been determined from Propositions 3 and 4 that the required trades will not satisfy *BB*. Therefore, the argument could be made that only with money would the individuals reveal what they knew. I shall not follow this course because the informational demands for the indirect exchange model appear to be complicated and are certainly exorbitant. The same argument can be more easily elaborated with the direct exchange model.[16]

PROPOSITION 6: *If trades must satisfy BB, the CE allocation is not informationally feasible in the direct exchange model.*[17]

The reasons for Proposition 6 are similar to those underlying Proposition 5. In the class of economies $\mathfrak{U}$, no commodity is in sufficient supply to serve merely as a balancing item; and it will not do to pay one's debts in just any commodity or commodities. If the *CE* allocation is to be achieved under *BB*, commodities used as payment by i in his trade with j must also be those which j can pass on to $k, \ldots,$ etc., so that they pass in just the right sequence and end up in just the right hands. But this involves the individuals in indirect trade whose informational demands they cannot meet.

Proposition 6 points to a feature of the medium of exchange distinguishing it from a standard I.O.U. *When money is used, the parties to the transaction are admitting their inability to predict with whom and how the account will be settled.*

Proposition 6 is important because of its relation to

PROPOSITION 7: *When BB is not imposed, the CE allocation is informationally feasible in the direct exchange model.*

The trading rule which demonstrates Proposition 6 is: for all i and t, $\pi^t(i)=j$, and $\rho_i^t=(\rho_{i1}^t, \ldots, \rho_{im}^t)$, let $\rho_{ic}^t, c=1, \ldots, m$ be such that

(13)

$$\rho_{ic}^t=\begin{cases} w_{ic}^t+\min\left[\,|a_{ic}-w_{ic}^t|,\ |a_{jc}-w_{jc}^t|\,\right] \\ \qquad \text{if } (a_{ic}-w_{ic}^t)\geq 0 \text{ and } (a_{jc}-w_{jc}^t)<0 \\ w_{ic}^t-\min\left[\,|a_{ic}-w_{ic}^t|,\ |a_{jc}-w_{jc}^t|\,\right] \\ \qquad \text{if } (a_{ic}-w_{ic}^t)<0 \text{ and } (a_{jc}-w_{jc}^t)\geq 0 \\ w_{ic}^t, \text{ otherwise} \end{cases}$$

The rule described by (13) is an example of what Ross Starr (1972) has called excess demand diminishing (*EDD*) trades. They follow the prescription "never engage in any trade which changes the sign of your excess demand." If you start out as a buyer of a commodity, do not accept more than you planned to purchase; and, if you start out as a seller of a commodity, do not give more than you planned to sell. The prescription is designed to prevent indirect or middleman trade.

It is clear that (13) satisfies the technical feasibility condition (6) and is informationally feasible since it requires only a knowledge of the trading pair's current excess demands, $(a_i-w_i^t)$ and $(a_j-w_j^t)$. It is a straightforward matter to show that (13) must always result in the *CE* alloca-

[16] The indirect exchange sequence, by explicitly denying the informational sufficiency of prices, provides the kind of environment hospitable to the activities of specialists in exchange. See Ostroy (1970). All of this is of a piece with money. Nevertheless, when our interest is just monetary exchange, we may use the direct exchange model to isolate the essential aspects of the problem in the context of a neater solution.

[17] Proofs of Proposition 6 follow along the lines of the demonstration of Proposition 5. Clearly, for $n=1$ and 2, it is false. It is also false for $n=3$. The reason is that once any two information sets $\{I_i^t\}$, $i=1, 2, 3$, are known the other may be inferred so there is effectively perfect information. Unless the additional assumption is made that individuals do not know their own trading histories, Proposition 6 is false for $n=4$. See Ostroy and Starr for a proof when $n\geq 5$.

tion if everyone is able to meet everyone else.

The merits of *EDD* trades are substantial. In terms of information, they are extremely economical and they lead, in the direct exchange (but not the indirect exchange!) model, to the *CE* allocation. They have demerits as well.

1. *EDD trades do not satisfy BB*. This is to be expected in light of Proposition 6. For emphasis, I shall add that they almost never satisfy *BB* (if $n>2$). To illustrate, consider the case of $W=I$, the identity matrix. Then, for all $(A, I)\in\mathfrak{U}$, *EDD* trades satisfy *BB* if, and only if, A is symmetric.[18]

2. *EDD trades do not form a utility increasing sequence.* Whenever $p\cdot(w_i^{t+1}-w_i^t)<0$, so that sales exceed purchases, we must admit the possibility that $u_i(w_i^{t+1})<u_i^t(w_i^t)$. Similarly, whenever $p\cdot(w_i^{t+1}-w_i^t)>0$, so that purchases exceed sales, we may have $u_i(w_i^{t+1})>u_i(w_i^t)$; and, if some of one's purchases are made before any of one's sales, we may have $u_i(w_i^t)>u_i(a_i)$! This agrees with everday experience. If you did not have to pay for your purchases your utility would be above what it otherwise is.

3. *EDD trades are unpredictable.* If an individual has a positive (negative) excess demand at the start of t, he cannot tell how much of it will be fulfilled (taken) during the period. To know this, he would have to know the entire configuration of initial excess demands as well as who met whom before t. This means that during the course of trade, an individual cannot determine whether he is on a path leading to his *CE* allocation or some other point. Only at $t=\tau+1$ does he know where he ends up. Suppose i does not end up at a_i because, to jump ahead, someone other than i misrepresented himself. Now, i knowns this was not his fault, but he cannot determine from his trading positions, $w_i^1, w_i^2, \ldots, w_i^{\tau+1}$, who was responsible. He cannot, for example, surmise that if $\pi^t(i)=j$, and $p\cdot(w_i^{t+1}-w_i^t)<0$, that j overstated his demands. It may have been that at period s, when $\pi^s(i)=k$, and $p\cdot(w_i^s-w_i^s)>0$, that individual k understated his supplies.

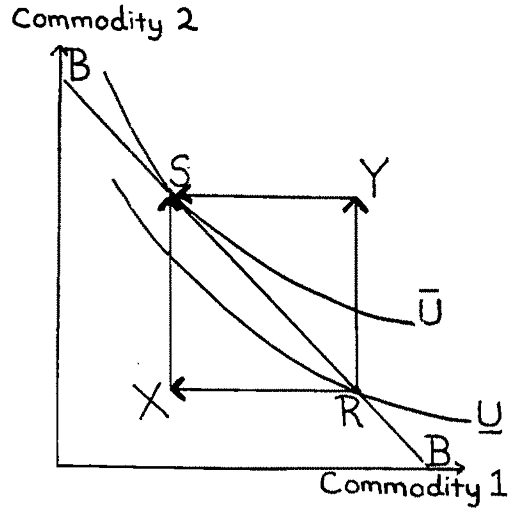

FIGURE 1

The above three features of *EDD* trades are illustrated in Figure 1. The straight line, *BB*, is the budget line. It goes through the initial endowment, point *R*, and the *CE* allocation, point *S*. The *EDD* trades begin and end on the budget line but in the interim they depart from it. The path $R\rightarrow X\rightarrow S$ indicates a trading sequence in which sale preceded purchase while the path $R\rightarrow Y\rightarrow S$ indicates the reverse. There is no guarantee that the intermediate posi-

[18] Applying (13) when $W=I$, we have that for any i and $\pi^t(i)=j$,

$$\rho_{ic}^t=\begin{cases} w_{ic}^t+a_{ic}, & \text{if } c=j \\ w_{ic}^t-a_{jc}, & \text{if } c=i \\ 0, & \text{otherwise}\end{cases}$$

Therefore, when $p=(r, r, \ldots, r), r>0, p\cdot(w_i^{t+1}-w_i^t)=0$ if, and only if, $a_{ij}=a_{ji}$.

tions, indicated here by the points X and Y, will lie within the region whose lower bound is $\underline{U}$, the indifference curve passing through the initial endowment, and whose upper bound is $\overline{U}$, the indifference curve passing through the CE allocation.

IV. Equilibrium

Recall that in defining the trading rule, $\rho=\{\rho_i^t\}$, it was assumed that individuals had no choice. Each revealed what he knew to the best of his knowledge. However, the trading rule does not require this accuracy. All that is required and all I shall assume is that no one says he has more of a commodity than he knows he has, although he may say he has less.

Let $h_i^t(I_i^t)=\hat{I}_i^t$ be the information i conveys to the broker. It is his decision whether or not to misrepresent what he knows. A strategy for i is a system $h_i=\{h_i^t(I_i^t)\}$, detailing what he will say he knows given what he actually knows at each trading opportunity. Therefore, $\{h_i^t\}$ rather than $\{I_i^t\}$ will be the informational inputs determining the course of trade.

Suppose a trading rule $\rho=\{\rho_i^t\}$ and strategies h_i^t, $i=1,\ldots,n$ have been selected. The outcome is uniquely determined by the initial state. If $S^1=(A, W^1; \pi)$, this determines $\{I_i^1(S^1)\}$ and therefore $\{h_i^1(I_i^1)\}$, and then $\{\rho_i^1(h_1^1,\ldots,h_n^1)\}$ which determines W^2 and therefore $S^2=(A, W^1, W^2; \pi),\ldots,$ etc. We may summarize this recursive relation by saying that if the initial state is $(A, W; \pi)$ and the trading rule is given by $\rho=\{\rho_i^\tau\}$ and individual strategies are given by $h_1,\ldots,h_n$, the end result is

$$g_i[\rho, h_1,\ldots,h_n \mid (A, W; \pi)] = w_i^{\tau+1}, \qquad i=1,\ldots,n$$

Now, we may say that *the CE allocation is an equilibrium* if for *all* $(A, W)\in\mathfrak{U}$ and $\pi\in\Pi_\tau$ there exists a trading rule $\rho^*=\{\rho_i^{*t}\}$ and strategies $h_1^*,\ldots,h_n^*$ such that for all $i=1,\ldots,n$,

$$(14)\qquad g_i[\rho^*, h_1^*,\ldots,h_n^* \mid (A, W; \pi)] = a_i$$

and

$$(15)\qquad u_i(a_i) = \max_{h_i} u_i(g_i[\rho^*, h_1^*,\ldots, h_i,\ldots,h_n^* \mid (A, W; \pi)])$$

The CE allocation is an equilibrium if the CE allocation is informationally feasible (14) and if it is in no individual's interest to depart from his strategy given the trading rule and strategies of the others (15).[19]

Underlying the question of the equilibrium of the CE allocation is the necessary condition of budget balance (BUB),

$$(16)\qquad p\cdot(w_i^{\tau+1} - w_i^1) = 0, \qquad i=1,\ldots,n$$

Over the course of trade, if not at each trade, (16) says the purchases and sales balance.

Supposing individuals to have no choice so that they are compelled to satisfy BUB, it follows immediately from the definition of the CE allocation (see (1)) that

PROPOSITION 8: *If the CE allocation is informationally feasible and if BUB is imposed the CE allocation is an equilibrium.*

If BUB were not imposed from outside, would individuals voluntarily choose strategies leading to it; i.e., would they choose to reveal what they know? If not, the CE allocation is not an equilibrium.

The only means the individuals have of imposing BUB amongst themselves is through BE. Suppose that all $i\neq j$ give instructions to their brokers that they will refuse to partake in any trade for which $p\cdot(w_i^{t+1}-w_i^t)<0$; then j cannot do other than satisfy BUB over the course of trade. If some i does not adhere to this, j is not

[19] Condition (15) is the definition of a noncooperative equilibrium proposed by John Nash.

constrained by *BUB*. It has already been determined (Proposition 6) that *BB* precludes the informational feasibility of the *CE* allocation in the direct exchange model. But to give up *BB* is to give up the incentive to reveal what one knows. The summary conclusion is

PROPOSITION 9: *The CE allocation is not an equilibrium for the direct exchange model.*[20]

Of course, if the individuals are willing and able to allow more time for trade, the opposite conclusion may be drawn. Consider the following "turn-taking" routine: Individual 1 goes to each of the others in turn asking for commodities to fulfill his (positive) excess demands and paying for them with his excess supplies so that *BB* is maintained. After $(n-1)$ periods he will reach his *CE* allocation. Next, 2 takes his with $3, \dots, n$ in the same manner, ..., etc., so that after $n(n-1)/2$ periods the *CE* allocation is achieved.[21]

V. Money as a Record-Keeping Device

How to enforce *BUB* without imposing *BB*? Rather than ask how this enforcement is actually effected, I shall focus on the conditions which must precede enforcement. Again, it is a matter of information.

Consider the direct exchange model and assume that if an individual who has "over-balanced" his budget—$p\cdot(w_i^{\tau+1}-w_i^1)>0$—is found out, he will be made to give up more than will put him back in balance; but if he is not found out, he may keep what he has. This represents a shortcut to the conclusions derived from a more extensive version (see Ostroy (1971)) which supposed that individuals were in an economy consisting of a large number of repetitions of the above direct exchange model.

At the completion of trade, we may ask i whether j balanced his budget. Recall from the definition of $I_i^{\tau+1}$, what he knows at the completion of trade, that i cannot say. Individual i knows only his own trading history and this will not suffice to infer what j has done. However, he does know one fact about j's trading history. At t, when $\pi^t(i)=j$, $p\cdot(w_j^{t+1}-w_j^t)=-p\cdot(w_i^{t+1}+w_i^t)$. If the information possessed by all $i\neq j$ were added together, we could compute $\sum_{t=1}^{t=\tau} p\cdot(w_j^{t+1}-w_j^t)=p\cdot(w_j^{\tau+1}-w_j^1)$. As it stands, however, this information is scattered among the individuals with no one other than j, himself, able to determine whether he has balanced his budget.

As a monetary version of the model of a trading economy, introduce a central receiving station called a monetary authority. Its function is to collect and collate the bits of information individuals have about each others' trading histories. Each will require his trading partner to write a signed statement, a check, indicating the amount by which the partner's purchases exceed his sales. This record is forwarded to the monetary authority who revises individual accounts on the basis of this new information. *Sellers, by requiring payment in money, are guaranteeing a steady flow of information such that the monetary authority, and it alone, is able to monitor trading behavior.* Of course, there is every incentive to require and deposit this information with the monetary authority; otherwise, one would not receive credit for sales and so have to cut back on purchases. Therefore,

[20] This result does not hold when $n<5$ (see fn. 17).

[21] This is an upper bound and not necessarily a minimum estimate of the number of periods required to make the *CE* allocation informationally feasible with *BB*. This result demonstrates that to achieve the same end additional time can be substituted for lack of information. The tradeoff may be pushed further. Allan Feldman has shown that when individuals know nothing but their own tastes and endowments but have an unlimited number of bilateral trading opportunities, if they accept only utility-increasing trades they will, under certain assumptions, eventually reach a Pareto optimal allocation.

PROPOSITION 10: *In the monetary version of the direct exchange model, the CE allocation is an equilibrium.*[22,23]

There is a small slip. We have seen that for any $(A, W) \in \mathfrak{U}$, any vector $p=(r, r, \ldots, r), r>0$, is a *CE* price vector. If the monetary authority is to be able to make trades between different individuals commensurable, they must all agree to the same value of r; i.e., we require a common unit of account. While this convention is essential to the operation of the record-keeping system, it is not identical to it. Money is not simply a unit of account.

VI. Conclusion: Integrating Monetary and Value Theory

In the Walras-Hicks-Patinkin tradition, the goal of monetary theory has been to present a picture of a money economy which would be a logical extension of the standard theory of value. Walras brought the equation of the offer and demand for money into line with the rest of his system by making a distinction between the stock of money, assumed to be without any utility of its own, and the "services of availability" of the stock which does contribute to one's well-being. Just as no inquiry is made into the sources of satisfaction from other goods, the services of availability are similarly unquestioned.

Recently, several theorists have suggested that it might be useful to dig a little more deeply.[24] While the traditional approach could be readily applied to determine why individuals might hold more or less money given that they valued it in certain ways in the first place, perhaps, just perhaps, it might clarify some contemporary monetary muddles if we asked why money is held at all.

This poses a dilemma. How to make money appear without making the standard theory disappear? Normal research strategy says that for a theory to be complete and consistent it must be derivable from the standard theory. But the standard theory has been cultivated to its present high level as a model of exchange in which money does not appear. Unlike the Walras-Hicks-Patinkin approach which left the standard theory intact and relied on conceptual appendages to introduce money, the recent approach forces us to look for modifications within the body of the theory. The following are some suppositions as to where to look on which I have not relied. I shall argue that they are superseded by the conclusions obtained from the above model of a trading economy.

1. *Money enlarges the set of feasible transactions.*[25] In the standard theory, any redistribution of commodities which preserves their totals is feasible. Into this model we can introduce the problems of exchange as a kind of transport cost of getting from one bundle of goods to another. We may then reason that monetary exchange represents a least cost network, so that without the money commodity the set of feasible transactions must shrink. While this may be adequate metaphorically, it misses the point. It is fairly well

[22] PROOF: Let h_i^* be such that $h_i^{*t}(I_i^t)=I_i^t$, $i=1, \ldots, n$ and let ρ^* be the *EDD* trades given by (13). These verify the first condition, (14), that the *CE* allocation is technically and informationally feasible.

The *assumed* informational and enforcement powers of the monetary authority make it clear to each individual that he cannot spend more than he earns so that besides the technical and informational restrictions, he must obey $p \cdot (w_i^{\tau+1}-w_i^1) \leq 0$. Therefore, if $h_j^t(I_j^t) \neq I_j^t$ for some j and t, then $u_j(w_j^{\tau+1}) \leq u_j(a_j)$. Since it is in each individual's interest to reveal accurately his excess demands, the remaining equilibrium condition, (15), is satisfied.

[23] I have avoided use of the term "transactions costs" because its meaning varies from writer to writer. However, the present treatment seems consistent with the the usage of my colleague, Earl Thompson, who defines transactions costs as those losses arising from differences in information. With his definition, we may say: Money reduces transactions costs.

[24] Compare fn. 2. That we recognize there is a problem at all is due largely to the important papers of Don Patinkin, Jacob Marschak, Hahn (1965), and Clower (1967).

[25] See Hahn (1971), Kurz, Niehans (1971) and Sontheimer.

established that the term "feasible" denotes what *could* happen, ignoring individual behavior, not what *would* happen. Monetary exchange does not enlarge the set of feasible transactions; it merely enables trades, which must be feasible in the first place to be realized.

2. *Money is held because we do not know what prices will be.*[26] Price uncertainty is neither necessary nor sufficient to explain the presence of a medium of exchange. The above model of a trading economy assumed that exchange rates were known; yet it required a record-keeping device. Suppose, however, that exchange rates were unknown but that individuals voluntarily agreed to keep accurate records of their transactions (in terms of a common unit of account) in order to balance their budgets. There would be no need for a medium of exchange.[27]

3. *The advantages of money have their origin in the properties of the money commodity.*[28] In the above model of a trading economy, all commodities are perfectly portable, durable, divisible, and recognizable, yet there is a need for money. The origin of this need is the decentralized trading arrangement. I chose to introduce a monetary authority and bookkeeping entries as a kind of ideal monetary arrangement because the record-keeping function of money is conceptually distinct from the properties of the commodities traded. Of course, to understand a particular monetary arrangement, it becomes a matter of recognizing a minimum cost method of imposing budget balance and in a society unfamiliar with double entry bookkeeping, the monetary version of the model of a trading economy would not be ideal. Then, bilateral balance might be the only means of insuring that individuals keep accurate records and balance their accounts and we would have to look for a minimum cost method of imposing bilateral balance. In such a situation, the principle would not change but the practice might well be to choose as a method of enforcing budget balance a commodity which is most portable, durable, divisible, and recognizable.

To the standard theory of value, the phenomenon of monetary exchange is surprising and distressing; surprising because the phenomenon is inexplicable and distressing because the phenomenon would seem to be one of the most elemental conclusions to be derived from any theory of exchange. Once we give up the standard theory framework which allows the execution of exchange to be the province of a centralized agency and concentrate on the logistics of more disaggregated trading arrangements, monetary exchange becomes explicable as a matter of course. It follows that these logistical considerations are worthy of attention by general equilibrium theorists.[29]

[26] See Radner.

[27] When individuals are groping for equilibrium exchange rates in a world where such voluntary restraint is lacking, monetary exchange would be essential. Imagine how much more difficult would be the approach to equilibrium if payment for one commodity were made in an arbitrary collection of other commodities. On this issue of price dynamics, I have benefited from reading Peter Howitt's study of stability in a decentralized regime of monetary exchange.

[28] See Brunner and Meltzer.

[29] See Donald Walker for a similar conclusion on the deficiencies of Walras' theory of exchange. Any reader familiar with the work of George Stigler and the contributors to Edmund Phelps et. al. will recognize that these logistical considerations have already received some attention as determinants of search unemployment in labor markets.

Externalities, Liability, Separability, and Resource Allocation

By JAMES R. MARCHAND AND KEITH P. RUSSELL*

"... only through a more detailed understanding of the way that supply externalities affect allocative outcomes can the efficacy either of organizational alternatives such as centralized industry management or of corrective devices such as taxes be considered with sufficient sophistication to yield any hope for reasonably efficient results."

Charles J. Goetz and
James M. Buchanan, p. 883

The study of resource allocation in the presence of externalities continues to be of great interest to economists. Primarily because of the welfare implications which arise from models characterized by interdependencies in production and/or consumption, such models are of great importance to policy makers. The purpose of this paper is to analyze and compare the allocative properties of a model containing externalities in which there are a number of alternative environments facing decision makers. Specifically, we postulate the existence of a production externality and analyze the effects on resource allocation of a) the imposition (or possible imposition) of liability for such externalities; and b) the solicitation of compensation or a bribe from the affected party by the externality generating firm. These environments are analyzed for both separable and nonseparable cost functions.[1] Our results indicate that the allocation of resources in these alternative environments is directly related to the form of the cost function.

In a widely quoted paper, Ronald Coase provides an analysis of the resource allocation effects of the imposition of liability upon a situation characterized by externalities.[2] In particular, he argues that, in a two-firm externality situation, imposition of liability by a legal authority on *either* party results in an efficient allocation of resources (i.e., the allocation of resources is unaffected by the disposition of liability). This result seems to have been accepted without reservation, see for example, George Stigler, Guido Calabresi, and Thomas Borcherding. The results presented here purport to show that Coase's conclusions are more restrictive than is generally believed. Specifically, we show that Coase's conclusion regarding the neutrality of liability on resource allocation holds only in the restricted case of additively separable cost functions.[3]

The questions considered here, especially the crucial role of separability, would seem to have been alluded to but never completely analyzed in the previous literature. In their article in *Economica*, Buchanan and William Stubblebine anticipate the differences between separable

* Assistant professor of economics, California State University, Northridge, and research associate, Human Resources Research Center, University of Southern California, respectively. The comments of Vittorio Bonomo, James Buchanan, Daniel Orr, Steven Huxley, and an anonymous referee are gratefully acknowledged. We retain responsibility for remaining errors.

[1] A function $f(x_1, x_2)$ is said to be separable if it can be written as $f(x_1, x_2)=f^1(x_1)+f^2(x_2)$. See Abraham Charnes and Carlton Lemke and Otto Davis and Andrew Whinston (1962).

[2] See also James Buchanan (1966), Guido Calabresi, Charles Plott, and Ralph Turvey. Also, E. J. Mishan (1965, 1971) critically discusses Coase's work, though along different lines than those followed here.

[3] As with Coase's original article, this paper deals explicitly with the case of a relatively small number of firms. See Section III for a further discussion of this point.

and nonseparable functions, although their model was formulated in terms of utility functions. Translating their analysis into arguments in terms of production functions, the link between their paper and ours would lie in a simple theorem, which gives the relationship between production functions and cost separability.[4] In a recent piece, William Baumol argues in favor of Pigovian (unilateral) taxes and subsidies to achieve optimal resource allocation and, while not explicitly considering separability, provides a model which is somewhat analogous to one of ours (see fn. 10). Davis and Whinston (1962) discuss separable versus nonseparable cost functions and the practical feasibility of imposing taxes and subsidies to achieve optimality. Two recent papers, by Goetz and Buchanan and by Lawrence Schall, analyze the competitive equilibrium and Pareto optimality characteristics of supply externalities with models similar to those developed here (see also Yasusuke Murakami and Takashi Negishi). These works do not, however, explicitly explore how separability affects resource allocation under alternative liability arrangements, which is one of our main purposes here.

Our analysis proceeds as follows. We assume the existence of two different, but interacting, productive activities. First, traditional models of these productive activities under different decision units or firms are considered. Here "traditional" is taken to mean similar to (or identical to) those used explicitly or implicitly in previous literature such as Frank Knight's well-known article, "Some Fallacies in the Interpretation of Social Cost," or in any intermediate textbook discussion of external diseconomies between firms in different industries. Next, the same situation is analyzed using models with a more complete and expanded view of profit maximization, which have been suggested by Coase. Thirdly, the analysis returns to the profit maximizing framework of the first model, but the assessment of liability is changed from that implied in the first case. Finally, the analysis concludes with a model of the activities under joint production, that is, one firm. From the first-order conditions yielded by these models and with some further assumptions about the shape of cost curves, we obtain interesting implications about resource allocation to be compared and evaluated.

I. Resource Allocation in Alternative Environments: Nonseparable Costs

A. *Profit Maximization under Externalities*

Consider two firms, A and B, each a member of a different competitive industry, whose productive processes interact. Denote A and B outputs as q_1 and q_2 and their total cost functions as $A(q_1)$ and $B(q_1, q_2)$, respectively. (These functions relate the costs of the inputs purchased directly by the firms to the levels of output indicated in the arguments.) Assume that $A_1>0, B_1>0, B_2>0, A(0)=0$, and $B(q_1, 0)=0$.[5] That is, we assume that production by firm A will raise the costs of firm B at any strictly positive output level that B chooses to produce: a case of external diseconomies.[6]

[4] THEOREM: *The cost function $C(q_1, q_2)$ is separable i.e., $C(q_1, q_2)=C^1(q_1)+C^2(q_2)$ if, and only if, $q_1=F(x, q_2)$ is separable, i.e., if, and only if, $q_1=F^1(x)+F^2(q_2)$* where *x is an input vector for the production of q_1.*

The proof of this is based on necessary conditions for cost minimization and is omitted here.

[5] For notational convenience we will use subscripts on the functions to indicate *both* partial and total derivatives. That is, $A_1=dA/dq_1$ while $B_1=\partial B/\partial q_1$. The context will make clear if we are discussing partials or totals.

[6] The interaction here is one way, and interdependence is, of course, feasible. The form chosen here simplifies the mathematics without altering the conclusions. In addition, the question of the existence of an equilibrium (as discussed by Davis and Whinston (1962)) is avoided.

In the unrestricted situation firm B bears the cost of the interaction; A is not liable for the extra cost it inflicts on firm B. When A and B face the market-determined output prices P_1 and P_2, respectively, simple models of these firms are:

Firm A: $\underset{\{q_1\}}{\text{Maximize}}\ P_1q_1 - A(q_1)$

subject to $q_1 \geq 0$

Firm B: $\underset{\{q_2\}}{\text{Maximize}}\ P_2q_2 - B(q_1, q_2)$

Subject to $q_2 \geq 0$

Thus, conventional theory concludes that the firms' output decisions, $\hat{q}_1$ and $\hat{q}_2$, must be such that:

$$P_1 = A_1(\hat{q}_1) \tag{1}$$

$$P_2 = B_2(\hat{q}_1, \hat{q}_2) \tag{2}$$

Since $B_1(q_1, q_2) > 0$, when $\hat{q}_1 > 0$ the profit-maximizing output level for firm B is lower than it would be in the absence of the externality.[7] This is, of course, the standard result of traditional behavior in the presence of externalities.

B. *An Expanded View of Profit Maximization*

One of the main arguments of "The Problem of Social Cost" by Coase is that in the case of undefined liability, the above model of firm A is incorrect. Coase states that ". . . a receipt foregone of a given amount is the equivalent of a payment of the same amount" (p. 7), and that, furthermore, the "injured" firm, B, should be indifferent to whether it bears an extra cost or pays compensation of an equal amount to avoid this extra cost. Thus firm A's costs must include the bribe it is foregoing in choosing to produce a particular level of output, for this is an opportunity cost of production. Assuming that firm A would choose to produce $\hat{q}_1$, this cost is the compensation which B would be willing to pay and is equal to the cost saving B receives as a result of A's producing less than $\hat{q}_1$; that is, compensation would be $C = (B(\hat{q}_1, q_2) - B(q_1, q_2))$. This argument may be put another way in terms of the net revenue of the productive activities of firm A. By producing $\hat{q}_1$ units and selling them at a price of P_1 the firm obtains the gross revenue $P_1\hat{q}_1$. However, at the same time, if it does not solicit the bribe from firm B, it is foregoing revenue in the amount of $B(\hat{q}_1, q_2) - B(q_1, q_2)$ which is the amount B is willing to pay to be rid of the costs A is imposing by producing $\hat{q}_1$ instead of q_1. Thus, firm A's net revenue from producing $\hat{q}_1$ instead of producing q_1 is $P_1\hat{q}_1 - [B(\hat{q}_1, q_2) - B(q_1, q_2)]$. Taking either the cost or the revenue approach, the models for firms A and B become (assuming that transactions are costless):[8]

$$\underset{\{q_1\}}{\text{Maximize}}\ P_1q_1 - A(q_1) + [B(\hat{q}_1, q_2) - B(q_1, q_2)]$$

subject to $q_1 \geq 0$

$$\underset{\{q_2\}}{\text{Maximize}}\ P_2q_2 - B(q_1, q_2) - [B(\hat{q}_1, q_2) - B(q_1, q_2)]$$

subject to $q_2 \geq 0$

The output decisions of the firms, q_1'' and q_2'', are such that:

[7] We conduct our analyses in terms of explicit increases in the costs of production rather than decreases in the profit levels to facilitate the exposition of the role of separability in our model. Since profits are just revenues minus costs, this approach is perfectly general and involves no restrictions.

[8] The formulation given in the text was suggested by an anonymous referee. In our original formulation, A's criterion function included the opportunity bribe that he might attain over the various alternative quantities that he could produce, rather than the bribe received if A took $\hat{q}_1$ to be his initial output position. In this case, the model for firm A becomes: Maximize $P_1q_1 - A(q_1) - [B(q_1, q_2) - B(0, q_2)]$. With the model for B unchanged, the equilibrium conditions remain (3) and (4).

(3) $\quad P_1 = A_1(q_1'') + B_1(q_1'', q_2'')$

(4) $\quad P_2 = B_2(\hat{q}_1, q_2'')$

C. *The Imposition of Liability*

Let us now suppose that a law or a judge were to declare firm A liable for the extra costs experienced by firm B in a state of nature. Liability is therefore $L = B(q_1, q_2) - B(0, q_2)$. In these circumstances the appropriate models of the firms would be:[9]

Firm A: Maximize$_{\{q_1\}}$ $P_1q_1 - A(q_1) - [B(q_1, q_2) - B(0, q_2)]$

subject to $q_1 \geq 0$

Firm B: Maximize$_{\{q_2\}}$ $P_2q_2 - B(q_1, q_2) + [B(q_1, q_2) - B(0, q_2)] = P_2q_2 - B(0, q_2)$

subject to $q_2 \geq 0$

In this case it is necessary that for the chosen outputs, q_1' and q_2'

(5) $\quad P_1 = A_1(q_1') + B_1(q_1', q_2')$

(6) $\quad P_2 = B_2(0, q_2')$

D. *Resource Allocation under Centralized Decision Making*

To find the outputs which are socially optimal one has to find the outputs which maximize the social product. One way of doing this is to internalize the externality by making both activities subject to one decision unit. When both productive activities are subject to one decision unit, the damage done and the costs incurred in the Bth activity due to the Ath activity must be recognized when the decision maker chooses the output level for the Ath activity. Thus, a profit-maximizing model of the joint firm is:

Maximize$_{\{q_1, q_2\}}$ $P_1q_1 + P_2q_2 - A(q_1) - B(q_1, q_2)$

subject to $q_1 \geq 0$, $q_2 \geq 0$

For the socially optimal outputs, q_1^* and q_2^*, it is necessary that:

(7) $\quad P_1 = A_1(\overset{*}{q_1}) + B_1(\overset{*}{q_1}, \overset{*}{q_2})$

(8) $\quad P_2 = B_2(\overset{*}{q_1}, \overset{*}{q_2})$

There are thus four (possibly different) outcomes to the resource allocation process, corresponding to the four alternative environments. For purposes of comparison, in Table 1 we present the output levels corresponding to each environment.

TABLE 1

Environment	Output
Case a: Traditional Profit Maximization	$\hat{q}_1, \hat{q}_2$
Case b: Expanded Profit Maximization	q_1'', q_2''
Case c: Imposition of Liability	q_1', q_2'
Case d: Centralized Decision Making	q_1^*, q_2^*

Without making further assumptions about the second-order partial derivatives of the cost functions, little can be said about the relationship of q_1^*, q_2^*, the socially optimal outputs, to the levels of output chosen in the three cases cited. However, if we assume that the determinant of second-order partial derivatives

$$\begin{vmatrix} A_{11}(q_1) + B_{11}(q_1, q_2) & B_{21}(q_1, q_2) \\ B_{12}(q_1, q_2) & B_{22}(q_1, q_2) \end{vmatrix}$$

is nonzero for all $q_1, q_2 > 0$, then the transformations represented by the marginal cost functions $A_1(q_1) + B_1(q_1, q_2)$ and

[9] An alternative formulation of the problem is as follows: Let

$$\overline{B}(q_1, q_2) = \max_{\bar{q}_1} [B(\bar{q}_1, q_2) - B(q_1, q_2)]$$

$\overline{B}(q_1, q_2)$ is an upper limit for the bribe firm A could extract from firm B if joint production is (q_1, q_2). Then an alternative objective function for firm A is

$$\underset{\{q_1\}}{\text{Maximize}}\ P_1q_1 - A(q_1) + \overline{B}(q_1, q_2) = P_1q_1 - A(q_1) + \max_{\bar{q}_1} [B(\bar{q}_1, q_2) - B(q_1, q_2)]$$

This formulation leads to the same result as that given in the text.

$B_2(q_1, q_2)$ are one-to-one. With this property and the assumption that $A_{11}(q_1)$, $B_{11}(q_1, q_2)$, $B_{12}(q_1, q_2)$, $B_{21}(q_1, q_2)$ and $B_{22}(q_1, q_2)$ are positive, it can be shown (see Appendix) that conditions (9), (10), and (11) hold:

$$\hat{q}_1 > \overset{*}{q_1} \quad \text{and} \quad \hat{q}_2 < \overset{*}{q_2} \tag{9}$$

$$q_1' < \overset{*}{q_1} \quad \text{and} \quad q_2' > \overset{*}{q_2} \tag{10}$$

$$q_1'' > \overset{*}{q_1} \quad \text{and} \quad q_2'' < \overset{*}{q_2} \tag{11}$$

Conditions (9) indicate that for firms which individually profit maximize, the outputs forthcoming will not be socially optimal. In addition, in neither the compensation case nor in the liability case will the outputs be socially optimal. In the former case, firm A's output is too large (as in the first case) while firm B's output is too small. This nonoptimality is independent of whether firm A obtains the bribe: if he does not, we have condition (9); if he does, we have (11). In the liability case, and this is one of our most important results, examination of (5), (6), and (10) indicates the outcomes. In this situation, the equilibrium condition for firm A appears to be optimal, but analysis of the second firm's condition indicates that it is not socially correct. This is due to the fact that if firm B is fully compensated for any cost increase due to the actions of firm A, then B's privately optimal decision will be calculated as if firm A were producing zero output; q_2' will thus be socially too large and q_1' will be socially too small, the reverse of the compensation (bribe) case. This is in direct contradiction to what Coase concludes: in his paper, he denies that "... the fact that the cattle-raiser [firm A] would pay for all crops damaged would lead the farmer [firm B] to increase his planting" (p. 3). Notice also that there is a similarity between the compensation case and the liability case, but with opposite results. These order relationships are not surprising since they simply reflect the well-known tenet that output falls as either the marginal revenue curve shifts down or the marginal cost curve shifts up, all other things held equal.[10]

Thus, only in the case in which there is joint decision making is there an optimal allocation of resources. If legal forces make firm A totally liable, or if firm A either receives or does not receive the bribe, there is a misallocation of resources: in these cases the allocation of resources is nonoptimal. For the "state of nature" in which all of the costs of the externality accrue to firm B and A does not solicit the bribe, A's marginal cost is understated and B's is overstated, socially. The result is that at given market prices A overproduces and B underproduces in social terms. A similar result occurs if A receives compensation from B. Placing total liability on the firm "generating" the external diseconomies creates an inverse nonoptimal allocation of resources. Because firm B is being totally compensated, its marginal costs are understated in relation to social cost and firm B is induced to overproduce. As firm A is bearing total liability, its marginal costs are overstated and it produces less than the socially optimal amount of output.

[10] Baumol discusses the effects of *unilateral* taxes (subsidies) on resource allocation and shows that these taxes do in fact generate socially optimal allocations. He also discusses practical methods for implementing such taxes to achieve optimality. In our notation, his model would be similar to the liability case except for B's criterion function:

firm A: Maximize $P_1q_1 - A(q_1) - [B(q_1, q_2) - B(0, q_2)]$
firm B: Maximize $P_2q_2 - B(q_1, q_2)$

First-order conditions are

$$P_1 = A_1(\tilde{q}_1) + B_1(\tilde{q}_1, \tilde{q}_2)$$
$$P_2 = B_2(\tilde{q}_1, \tilde{q}_2)$$

which are identical to (7) and (8), i.e., the socially optimal allocations. Thus $\tilde{q}_1 = q^*$, $\tilde{q}_2 = q^*$. As shown below, however, with separable cost functions unilateral taxes are not the only means of generating a socially optimal allocation.

II. Resource Allocation in Alternative Environments: Separable Costs

With the framework developed in Section II, the analysis of the same types of environments but with separable cost functions is quite straight-forward.[11] Under the assumption of separability, firm B's cost function will now be written[12]

$$B(q_1, q_2) = b^1(q_1) + b^2(q_2) \text{ with } \overset{1}{b_1}, \overset{2}{b_1} \geq 0.$$

The remainder of the analysis consists simply of substituting this cost function into the previous models and determining the first-order necessary conditions. The models are as follows, with first-order conditions corresponding to (1)–(8) denoted by (1′)–(8′).

A. *Traditional Profit Maximization*

Under conditions of separability of the cost functions, models of the firms become:

Firm A: $\underset{\{q_1\}}{\text{Maximize}}\ P_1q_1 - A(q_1)$

Subject to $q_1 \geq 0$

Firm B: $\underset{\{q_2\}}{\text{Maximize}}\ P_2q_2 - b^1(q_1) - b^2(q_2)$

subject to $q_2 \geq 0$

In this case, the conditions corresponding to (1) and (2) above are:

$$(1') \qquad P_1 = A_1(\hat{q}_1)$$

$$(2') \qquad P_2 = \overset{2}{b_1}(\hat{q}_2)$$

B. *Compensation Case*

In this case, we have the following:

Firm A: $\underset{\{q_1\}}{\text{Maximize}}\ P_1q_1 - A(q_1) + [b^1(\hat{q}_1) + b^2(q_2) - b^1(q_1) - b^2(q_2)]$

subject to $q_1 \geq 0$

Firm B: $\underset{\{q_2\}}{\text{Maximize}}\ P_2q_2 - b^1(\hat{q}_1) - b^2(q_2)$

subject to $q_2 \geq 0$

Profit maximization conditions become

$$(3') \qquad P_1 = A_1(q_1'') + \overset{1}{b_1}(q_1'')$$

$$(4') \qquad P_2 = \overset{2}{b_1}(q_2'')$$

C. *The Imposition of Liability*

The models under conditions where liability is imposed are:

Firm A: $\underset{\{q_1\}}{\text{Maximize}}\ P_1q_1 - A(q_1) - [b^1(q_1) + b^2(q_2) - b^1(0) - b^2(q_2)]$

subject to $q_1 \geq 0$

Firm B: $\underset{\{q_2\}}{\text{Maximize}}\ P_2q_2 - b^1(0) - b^2(q_2)$

subject to $q_2 \geq 0$

Conditions (5) and (6) then become

$$(5') \qquad P_1 = A_1(q_1') + \overset{1}{b_1}(q_1')$$

$$(6') \qquad P_2 = \overset{2}{b_1}(q_2')$$

D. *Centralized Decision Making*

Finding conditions which maximize the social output give:

$\underset{\{q_1, q_2\}}{\text{Maximize}}\ P_1q_1 + P_2q_2 - A(q_1) - b^1(q_1) - b^2(q_2)$

subject to $q_1, q_2 \geq 0$

Maximum conditions are

$$(7') \qquad P_1 = A_1(\overset{*}{q_1}) + \overset{1}{b_1}(\overset{*}{q_1})$$

$$(8') \qquad P_2 = \overset{2}{b_1}(\overset{*}{q_2})$$

For this case, since $B_{12}(q_1, q_2) = B_{21}(q_1, q_2) = 0$, when one assumes that $A_{11}(q_1)$, $b^1_{11}(q_1)$, and $b^2_{11}(q_2)$ are positive for $q_1, q_2 > 0$,

[11] This is the case which Coase analyzed through the use of several numerical examples. His analysis concluded that the allocation of resources was independent of the definition of liability, but that this definition did determine the distribution of income (i.e., returns). See also Warren Nutter for additional numerical examples and an analysis similar to that of Coase.

[12] Recall that $b_1^1(q_1) = db^1/dq_1$; $b_1^2 = db_2^2/dq_2$.

it is possible to show that (see Appendix):

$$(9') \quad \overset{*}{q}_1 = q_1'' = q_1' \quad \text{and} \quad \overset{*}{q}_2 = q_2'' = q_2'$$

and

$$(10') \qquad \hat{q}_1 > \overset{*}{q}_1 \quad \text{and} \quad \hat{q}_2 = \overset{*}{q}_2$$

With separable cost functions the results of our analysis of resource allocation show lesser variation. If firm B's cost function is separable and firm A is the type of profit maximizer hypothesized by Coase, then the definition of liability for the costs of interaction does not affect the output decisions; they are socially optimal in either case. Only if firm A neither takes the bribe nor pays for the external costs it causes, is there a misallocation of resources.

III. Qualifications

It should be noted that the analysis which has been presented above has passed over several theoretical points and therefore must be qualified. The most serious shortcoming of this study is that it makes no distinction between *threatened* quantities and *actual* quantities.[13] In certain of the instances there may exist an incentive for firm A to threaten to produce a quantity greater than that which is optimal, in order to induce firm B to pay a higher bribe. (Of course, there are also cases in which firm A would have an incentive to understate his optimal output, for example, in the case of assigned liabilities.) In certain instances the [heroic] assumptions of perfect knowledge might vitiate this criticism. The analysis of a world of uncertainty where we can determine bounds on threatened quantities and determine each firm's optimal strategy using game-theoretic methods will be the topic of a forthcoming paper.

[13] On this, see G. A. Mumey. His conclusions that misallocations may arise from threats used as revenue generators and from coercive income distributions are independent of our conclusions.

Another point is that it may be quite fictitious to analyze two competitive firms in this type of situation. One either must leave the two-firm framework or drop the assumption of competitive organization. The homogeneity postulate of the theory of perfect competition requires that all firms in an industry face the same total cost situation. Thus, it is only theoretically correct to anlyze the interaction of two competitive industries. This extension would yield the same qualitative results for the individual firm. However, changing the firms' marginal cost curves requires changing the industries' supply curves implying that the price of the output and the number of firms would differ with different assignments of liability. This, of course, only further magnifies the shifts in the allocation of resources.

If one chooses to remain in a two-firm framework, then one might examine models of monopoly. This problem, however, seems to have been adequately analyzed in the literature (see, for example, Buchanan (1969)).

Also, though both firms were assumed to be members of competitive industries, the cost functions used here must be inclusive of Ricardian rents. This is necessary because, as Stanislaw Wellisz has said:

> In a perfectly competitive industry in which there are no Ricardian rents, external diseconomies result in factor use changes without creating any social costs. In such a setting every firm operates at a zero profit level and all the factors are paid their opportunity costs. If external costs are imposed upon one of the competitive units, that unit will make losses and in the long run go out of business. [p. 350]

Finally, it is possible that one might argue against our results on the grounds that we did not allow the individuals concerned sufficient scope to negotiate. That is, no matter what liability rule is in effect, any arrangements are preliminary in

nature and lead to more complex negotiations such that it is possible for individuals to merge and attain the jointly optimal solution. This notion of gains-from-trade in externality situations has been discussed by Buchanan and Stubblebine and by Baumol, and it is indeed possible that within the context of such negotiations a "generalized" Coase theorem might hold: that is, the jointly optimal solution is obtained independently of the assignment of liability or the liability rule in effect. This result would apply to both separable and nonseparable cases.

There are, however, several points to be considered before one can assume the validity of the generalized Coase theorem. In the first place, as noted by Baumol, in any practical situation the large numbers of transactors involved may make negotiation prohibitively expensive. In this case, the burden of proof in favor of a generalized Coase theorem would seem to lie with those who can show how such bargaining could take place: one cannot just assume that it does. Secondly, as noted in Baumol's paper, once such (private) gains are realized the resulting solution may in fact be nonoptimal (though, as Baumol shows, not through income effects as Buchanan and Stubblebine originally implied). Thus, while not rejecting the possibility of a generalized Coase theorem, we recognize that such a theorem could exist only under more fully specified conditions.

IV. Conclusion

The analysis above was begun with the idea of clarifying some issues concerning the type of resource allocation obtained under technological externalities in production. In particular, our analysis clarifies the question of the effect of making externality "generators" liable for external diseconomies. Neither from Coase's original analysis nor from the analysis developed herein can one universally say as Coase has said:

> It is necessary to know whether the damaging business is liable or not for damage caused since without the establishment of this initial delineation of rights there can be no market transactions to transfer and recombine them. But the ultimate result [i.e., the allocation of resources] (which maximizes the value of production) is independent of the legal position if the pricing system is assumed to work without cost. [p. 8]

This type of statement can only be made in the simple framework of separable cost functions. In the more complicated, yet more realistic world where production externalities involve nonseparable cost functions, the allocation of resources is not independent of the legal framework. As the inequalities in (9)–(11) show, the allocation of resources depends on the definition of liability.

In addition to indicating conditions under which Coase's conclusion does and does not hold, the analysis of the nonseparable cases points to the following summary The problem of social costs is a problem of joint costs. As Coase has said, "If we are to discuss the problem in terms of causation, both parties should take the harmful effect (the nuisance) into account in deciding on their courses of action" (p. 13). Firms on both sides of the problem must adjust their factor inputs and outputs to get the proper resource allocation. If one or the other side of the problem bears these costs alone, there will be a misallocation of resources.

The growth of problems involving questions of externalities, liability, and decision making under alternative institutional structures and the continuing interest of economists, policy makers, and the general public makes it imperative that the economics of these issues be made clear.

Appendix

In this Appendix we present simple proofs which are used in the body of the paper to indicate the relationships between output levels under alternative regimes.

Proof of (9)

1. For a given P_1, P_2 we can equate the right sides of equations (1) and (7) yielding

$$A_1(\hat{q}_1) = A_1(\overset{*}{q_1}) + B_1(\overset{*}{q_1}, \overset{*}{q_2})$$

Since $B_1(q_1^*, q_2^*) > 0$ by assumption, then $A_1(\hat{q}_1) > A_1(q_1^*)$. Assuming that $A_{11}(q_1) > 0$ then, $\hat{q}_1 > q_1^*$.

2. Equating the right half of equations (2) and (8) we find $B_1(\hat{q}_1, \hat{q}_2) = B_2(q_1^*, q_2^*)$. Since by assumption $B_{21}(q_1, q_2) > 0$ and $B_{22}(q_1, q_2) > 0$, then $\hat{q}_1 > q_1^*$ implies that $q_2^* < \hat{q}_2$.

Proof of (10)

1. By equating the right half of (6) and (8) we have that $B_2(0, q_2') = B_2(q_1^*, q_2^*)$. Since $q_1^* > 0$ and by assumption $B_{21}(q_1, q_2) > 0$ and $B_{22}(q_1, q_2) > 0$, then $q_2' > q_2^*$.

2. Equating the right half of (5) and (7) one finds

$$A_1(q_1') + B_1(q_1', q_2') = A_1(\overset{*}{q_1}) + B_1(\overset{*}{q_1}, \overset{*}{q_2})$$

Since we have assumed $B_{12}(q_1, q_2) > 0$ and $q_2' > q_2^*$, $B_1(q_1^*, q_2') > B_1(q_1^*, q_2^*)$. With $B_{11}(q_1, q_2) > 0$ suppose $q_1' \geq q_1^*$, then $B_1(q_1', q_2') \geq B_1(q_1^*, q_2') > B_1(q_1^*, q_2^*)$. Now $q_1' \geq q_1^*$ implies since $A_{11}(q_1) > 0$, that $A_1(q_1') \geq A_1(q_1^*)$. Subtracting this inequality from the first equation of this section one finds that $B_1(q_2', q_2') \leq B_1(q_1^*, q_2^*)$. This is a contradiction, thus we must have that $q_1' < q_1^*$.

Proof of (11)

1. Equating the right-hand sides of equations (4) and (8), we have $B_2(\hat{q}_1, q_2'') = B_2(q_1^*, q_2^*)$. Since $\hat{q}_1 > q_1^*$ and $B_{21}(q_1, q_2) > 0$, then $q_2'' < q_2^*$

2. Using equations (3) and (7), we have

$$A_1(q_1'') + B_1(q_1'', q_2'') = A_1(\overset{*}{q_1}) + B_1(\overset{*}{q_1}, \overset{*}{q_2})$$

The condition that $q_2'' < q_2^*$ requires for equality that $q_1'' > q_1^*$.

Proof of (9′)

The assumption of positivity of all the second-order partials is sufficient to insure that the Jacobian of the marginal cost functions is nonzero. This means that the two marginal cost functions represent a one-to-one transformation and that for the point P_1, P_2 in the image the arguments of the marginal cost functions must be unique. Thus

$$q_1'' = \overset{*}{q_1} = q_1' \quad \text{and} \quad q_2'' = \overset{*}{q_2} = q_2'$$

Proof of (10′)

1. Since our basic assumption is that $b_{11}^2(q_2) > 0$, $b_1^2(q_2)$ is a monotonic function. Thus $\hat{q}_2 = q_2^*$.

2. Through equating the right side of (1′) and (7′) one determines that $A_1(\hat{q}_1) = A_1(q_1^*) + b_1^1(q_1^*)$. By assumption $b_1^1(q_1^*) > 0$, thus $A_1(\hat{q}_1) > A_1(q_1^*)$. Since $A_{11}(q_1) > 0$ for $q_1 > 0$, then $\hat{q}_1 > q_1^*$

Assets, Subsistence, and The Supply Curve of Labor

By Yoram Barzel and Richard J. McDonald*

The "backward bending" supply curve of labor is now accepted as a matter of course by most economists. It has no doubt been perplexing to observe that the most commonly employed types of utility functions do not yield such curves under the usual textbook analysis of the problem.[1] Particular preference maps have been found that generate backward bending curves;[2] however, they are nonparametric, leading to difficulties of estimation, and upon closer examination seem to imply counter-intuitive results. We will show that taking into account the wealth position of an individual on the one hand and survival consideration on the other greatly expands the variety of shapes that can be derived for the supply curve from some simple utility functions. The use of a specific simple utility function also implies some severe restrictions on the form the supply curve can take, rendering it testable. Empirical evidence is shown to support the conclusion that the supply curve is monotonic. We will also show that the notion that the aggregate supply curve of labor slopes down rests, in part, on an error of aggregation, and that the empirical evidence usually cited in support of the negative slope, when correctly interpreted, cannot be so construed.

I. The Supply Curve of the Individual

A curious method is commonly employed to derive the accepted shape of the supply curve of labor. The typical text first points out (following Lionel Robbins) that a wage change results in an income as well as a substitution effect and, noting the importance of leisure in the individual budget, concludes reasonably enough that the supply curve may, in some of its range, have a negative slope. But then the discussion proceeds without further analysis to suggest something about a turning point in the curve—that the curve will turn back only after an initial positive slope. In Milton Friedman's words, " . . *beyond* some point the income effect dominates the substitution effect" (1966, p. 204, italics added) and the change in sign is explained by the statement that ". . . in a primitive society, the initial low wage rate at which the income effect becomes dominant reflects a lack of familiarity with market goods and a limited range of tastes. As tastes develop and knowledge spreads, the point at which the income effect dominates tends to rise." The sign change seems to apply only to a primitive society, the value at which this occurs seems to shift around, and its explanation is rather lame. Although Friedman is only one of many economists to accept uncritically the backward bending shape of the supply curve,[3] his argument is singled out precisely because of his usual astuteness and the advanced nature of the text.[4]

* University of Washington. Some of the work on this paper was done while Barzel was visiting University College, London, supported by a Ford Foundation Fellowship.

[1] For example, a Cobb-Douglas utility function yields a perfectly inelastic supply curve.

[2] See, for example, Giora Hanoch.

[3] J. R. Hicks apparently was the first to introduce the backward bend, but he failed to offer any satisfactory explanation.

[4] To cite one more example, Paul Samuelson in his elementary text also subscribes to the backward bending shape of the supply curve.

Consider now a point on the supply curve of labor and observe what happens to the income change due to *successive* wage increases. The effect of the first wage increase is independent of whether the supply curve at that point has a positive or a negative slope, not those of the second and subsequent wage changes. If the supply curve has a positive slope, the number of hours affected by subsequent wage changes is larger and, other things equal, the income effect tends to grow stronger and stronger.[5] The converse will occur if the income effect dominates in the first place, rendering the slope of the supply curve negative. These "self-correcting" tendencies give some basis for expecting the supply curve to eventually become vertical.

The asset holdings of the individual play an important (and thus far largely neglected) role in determining the shape of the supply curve of labor.[6] If we consider an extremely wealthy individual, it seems intuitively clear that as long as work itself is not a commodity, no labor will be offered at the lowest range of wages; assuming continuity of preferences and the absence of indivisibilities, an infinitesimal amount will be supplied at the point of entry into the labor market. From there, at least for awhile, the curve *has* to slope upwards.

On the other hand, for an individual with no wealth whatsoever and no income source other than his own work, the very lowest wage will be insufficient for survival. As wages increase, a point will be reached where survival becomes possible if he supplies the highest physically possible amount of labor. For such an individual, as the wage rate continues to rise, the amount of labor supplied *cannot* increase; given that leisure is a commodity, the supply curve has to have a negative slope right from its *very beginning*. It will be suggested in the following analysis that we predominantly observe just such an initially negatively sloped curve eventually tending to become perfectly inelastic.

To proceed with the formal analysis, we consider an individual who derives satisfaction from the consumption of two goods: market purchased commodities, denoted by C, and leisure, denoted by R. Assume that the preferences of the individual can be characterized by a function $f(C', R')$, which at a point (C', R') in the commodity space indicates the individual's marginal rate of substitution between the two commodities at that point.

That is,

$$\frac{dC'}{dR'} = -f(C', R')$$

for small movements leaving the consumer as well off as he was before. The accepted range of this function is for $C', R' \geq 0$. But it should be recognized that unless some positive level of consumption of C is reached, survival is not possible, and so for some positive values of C a preference map cannot be said to exist. Similarly, survival considerations may dictate a certain minimal level of leisure (or rest) time. Notice that the roles played by the two survival requirements are not symmetric since all individuals are endowed with more time than is needed for survival but not all have sufficient assets for survival. Denote by S the minimal required consumption of goods per day, and by T the minimal required leisure time and define C and R as $C = C' - S$ and $R = R' - T$. We now assume that the arguments in the marginal rate of substitution are C and R so that

[5] Of course, it is possible that as wages rise the rate of change of labor supply, with respect to a change in income, may change sufficiently to negate this tendency.

[6] Kenneth Boulding notes the role of assets but does not proceed to examine it fully (pp. 800–01). He, too, draws a backward bending supply curve of labor even though his illustrations (pp. 210–11) demonstrate only a negative slope and not a turning point.

$$(1) \qquad \frac{dC}{dR} = -f(C, R)$$

along an indifference curve, for C, $R>0$. This transformation, while innocuous as long as f is not further specified, is a substantive one once specific properties are assumed for the preference map, as we shall do below. We also assume that $f(C, R)$ is positive, differentiable, and that preferences are characterized by a diminishing marginal rate of substitution. Thus

$$(2) \quad \frac{d^2C}{dR^2} = f(C, R)f_1(C, R) - f_2(C, R) > 0$$

for movements along an indifference curve, and for all C, $R>0$, where f_1 and f_2 are, respectively, the partial derivatives of f with respect to C and R.

The individual is subject to constraints on time and expenditures. The time constraint is $R+T+L=D=24$, where D is the length of the day and L is labor hours.[7] Given the notion of required rest time, it is more convenient to write the constraint as

$$(3) \qquad R + L = D - T = D'$$

where D' is the fixed number of hours whose composition can be allocated to leisure or labor.

The expenditure constraint is $Y=WL+PA=PC'$, where Y is money income, W is the money wage rate (or the shadow wage if the individual is self-employed), P is the price of market commodities, and A is per day nonwage income in units of consumption goods. By rearranging and substituting from (3) for L, we get

$$(4) \qquad C + wR = wD' + A - S$$

where $w=W/P$. Equation (4) has as its variables C and R, the two arguments in the marginal rate of substitution. Notice that if $wD'<S-A$, then even if the individual works the physically maximum number of hours, he will not earn enough to survive. In other words, unless the condition

$$(5) \qquad w > \frac{S - A}{D'}$$

is satisfied, C and R cannot both be positive, and the function f is not defined.

We assume that the individual chooses the most preferred combination that he can attain, given that he is able to survive.[8] Necessary and sufficient conditions for this to be the bundle (C_0, R_0), given (5), are that C_0 and R_0 satisfy the equations (2) and (4), together with

$$(6) \qquad f(C_0, R_0) = w$$

This last condition is independent of the transformation previously imposed on the origin of the function f.

Comparative statics results can be obtained by differentiating conditions (4) and (6) partially, first with respect to A and then with respect to w. The resulting slopes of the demands for consumption and leisure with respect to the wage rate are

$$(7) \quad \frac{\partial C}{\partial w} = f/(ff_1 - f_2) + (D' - R)\frac{\partial C}{\partial A}$$

$$(8) \quad \frac{\partial R}{\partial w} = -1/(ff_1 - f_2) + (D' - R)\frac{\partial R}{\partial A}$$

Now we want to concentrate on the effects of wage changes on the quantity of labor supplied. Because of equation (3) we can write

$$(9) \quad \frac{\partial L}{\partial w} = 1/(ff_1 - f_2) - (D' - R)\frac{\partial R}{\partial A}$$

The first term of the right-hand side of

[7] No substantive change is involved if we carry the analysis in terms of some other time unit, such as a week or a year. More importantly, our analysis is equally relevant to market-employed as to self-employed individuals.

[8] If $wD'=(S-A)$, the consumer will thus choose $C=0$, $L=D'$ rather than to work less and starve.

(9) is the pure substitution effect and is necessarily positive, due to the convexity of the preference map. The second term, assuming that leisure is not an inferior commodity, is also positive but is preceded by a minus sign. It is clear from this formulation that without further specification of the consumer's preferences, it is impossible to say which of the two effects will dominate.[9] Notice, however, that if we are in a region where the income effect dominates, as w increases the term $(D'-R')$ is declining, tending to diminish the strength of the entire income term. The converse is true if the substitution effect dominates.

We now introduce a more specific form of the consumer's preference. This will allow more definite and more readily refutable empirical implications. The more detailed specifications will be introduced in two steps. First, the function $f(C, R)$ will be restricted to be homothetic. In this case the marginal rate of substitution between (net) consumption and leisure is a function only of the ratio in which the two goods are consumed. Equation (9) can now be rewritten as

$$\frac{\partial L}{\partial w}=\frac{1}{w}\,\frac{R}{(C+wR)}\,[C(\sigma-1)+(A-S)] \tag{10}$$

where σ is the elasticity of substitution between net consumption and net leisure.[10] So the slope of the supply curve depends on the signs of $(\sigma-1)$ and of $(A-S)$.[11] In the special case $\sigma=1$, where the preferences imply a Cobb-Douglas type of utility function, the sign of the slope of the supply curve hinges entirely on the sign of $(A-S)$. In general σ need not be constant but will vary with the ratio C/R. Letting $x=C/R$, it can be shown that

$$\frac{\partial\sigma}{\partial w}=\frac{1}{x}\,(1-\sigma-\sigma\epsilon)$$

where ϵ (itself a function of x) is defined by

$$\epsilon=\frac{h''(x)\cdot x}{h'(x)}$$

and $h(x)$ is the marginal rate of substitution as defined in the Appendix. Then, using the definition of σ, we have

$$\frac{\partial\sigma}{\partial w}=\frac{\sigma}{w}\,(1-\sigma-\sigma\epsilon)$$

and since our assumptions about the preference map impose no restrictions on the sign or magnitude of ϵ, nothing a priori can be said about the direction of change of σ as wages vary. Thus, if we do not restrict σ to a constant value, the supply curve can assume virtually any shape and therefore will have no testable implications.

The second step in specifying preferences, then, is to constrain σ to a constant value. This will also further simplify matters and allow for easy graphical interpretation. The marginal rate of substitution takes the particular form

$$f(C, R)=\left(\frac{1-\alpha}{\alpha}\right)\left(\frac{C}{R}\right)^{1/\sigma} \tag{11}$$

where $0<\alpha<1$.[12] The above assumptions

[9] If consumption C is assumed to be a normal good, then the demand for it (with respect to w) must be positively sloped, due to the restriction that the individual can consume no more than D' hours of leisure.

[10] See the Appendix.

[11] The terms in the square brackets in (10) are grouped differently than is conventional. Since $A-S-C=-wL$, these terms represent the income effect, while $C\sigma$ represents the substitution effect.

[12] Equation (11) would follow from any monotonically increasing function of the *CES* utility function.

$$V(C, R)=[\alpha C^{-\beta}+(1-\alpha)R^{-\beta}]^{-1/\beta} \qquad \text{for } \beta\neq 0$$
$$V(C, R)=C^{\alpha}R^{1-\alpha} \qquad \text{for } \beta=0$$

defined for $0<\alpha<1$ and $-1<\beta<\infty$. The elasticity of substitution is then equal to $1/(1+\beta)$. This specification is a generalization of the class of utility functions generating the so-called linear expenditure system of demand equations introduced by Laurence Klein and Herman Rubin, and more recently adopted by Richard Stone.

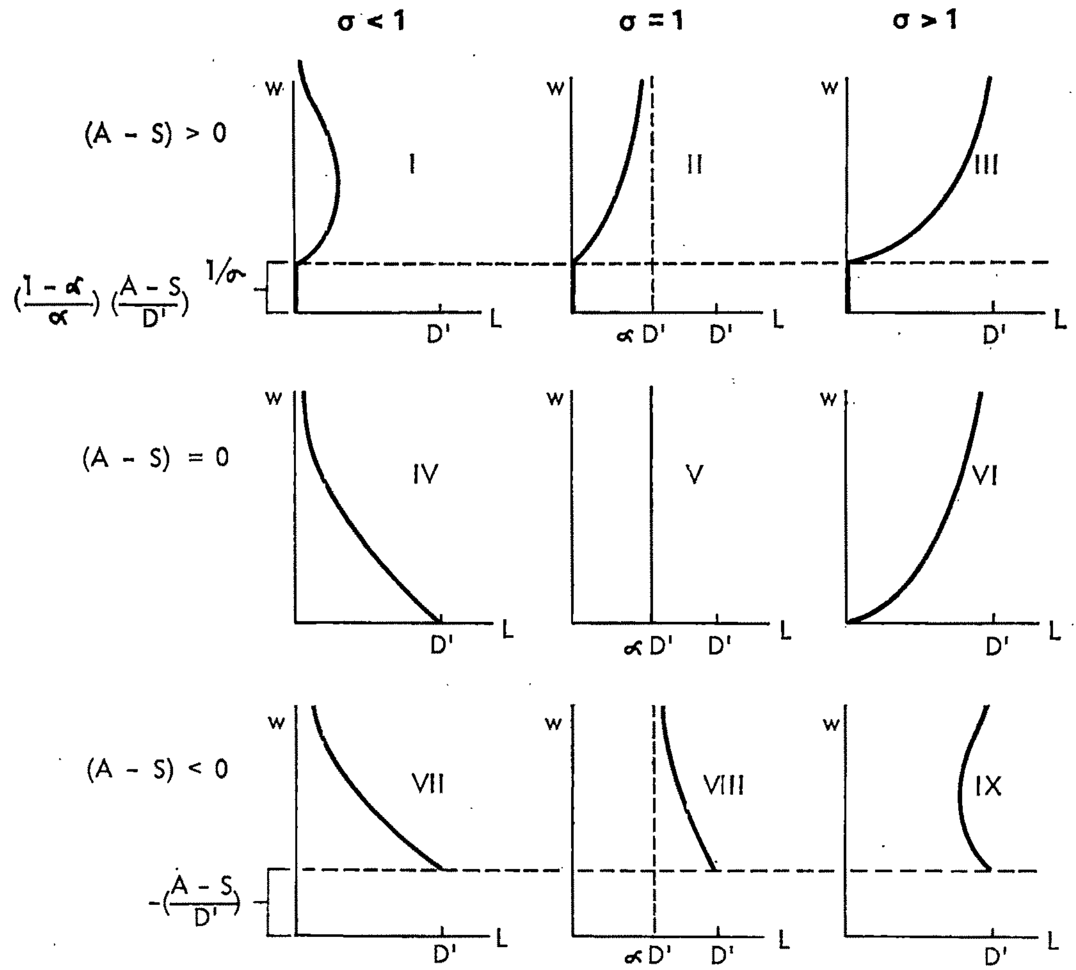

FIGURE 1

may appear to be highly restrictive; nevertheless, depending on the signs of $(\sigma-1)$ and $(A-S)$, we get the textbook characterizations of the supply curve as well as some novel ones.

The nine panels in Figure 1 are drawn for cases where $\sigma \gtreqless 1$ in combination with $(A-S) \gtreqless 0$. This set of diagrams gives us a whole gamut of possible results—monotonically rising and falling, perfectly inelastic, and both backward and forward bending. So the assumptions made regarding the form of the preference map do not turn out to be as restrictive as might first appear.[13] Notice that in the three figures with $(A-S)<0$ the supply curve is not defined for wage rates below $(S-A)/D'$.

The second row of panels (IV–VI) where $A-S=0$ corresponds to the conventional treatment of the supply of labor where both A and S are implicitly assumed equal to zero. It is easy to see, by comparing the second row with the first and with the third, the crucial importance of these two

[13] One important restriction is the linearity of the Engel curves. See Samuelson (1948). Given our subsistence requirements, the Engel curves do not necessarily go through the origin.

factors.[14] If assets are large enough, the supply curve will always have an initial region with a positive slope (and will be monotonic for $\sigma \geq 1$). If assets alone are insufficient to provide for survival, the supply curve will always slope negatively initially (and will be monotonic for $\sigma \leq 1$).[15] Consider an individual possessing no income source other than his own labor. If we do not explicitly take into account survival considerations, then the second row will appear pertinent. An individual with a utility function leading to $\sigma > 1$ would, at the lower wage range, then prefer to die from starvation rather than to earn enough for survival. This absurd result points to the reasonableness of transforming the preference function as we did.

There is no a priori reason to accept any one of these cases. It is important to note, however, that since few individuals, even in Western countries, start their working career with asset holdings sufficient for survival, the third row of diagrams represents the wealth conditions of most individuals. For some individuals, however, $A > S$; for those, we should observe, at least in part of the range, a positive relation between wages and hours, and in such cases the vertical intercept itself will rise with the level of asset holdings. It will be shown that empirical evidence conforms closely to the *C-D* case illustrated in Panel VIII.

II. The Negative Income Tax and the Supply of Labor

The preceding analysis can easily be adapted to determine the effects on the supply of labor of a variety of tax and transfer schemes. Of current interest are those tagged as "guaranteed annual income" or "negative income tax." Under most of these the individual whose income exceeds some "break-even" level, denoted here by Y_b, is being taxed and the individual whose income falls short of that level is being subsidized. For simplicity let us assume that the marginal rate of tax does not vary with income, that is, the rate of tax (which is also the rate of subsidy) is constant. If we denote this rate by t, the floor on income is tY_b.

The disposable income available to the individual, denoted by Y_d, is given then by

$$Y_d = Y + t(Y_b - Y) \tag{12}$$

where $Y = wL + A$. The budget constraint now becomes, after manipulations similar to those used to derive (4),

$$C + (1 - t)wR = (1 - t)(wD' + A) + tY_b - S \tag{13}$$

$$= (1 - t)wD' + (A - S) + t(Y_b - A) \tag{13'}$$

The condition for an interior maximum is now

$$f(C, R) = (1 - t)w \tag{14}$$

Again, assume the preference map to be homothetic, then the same comparative static techniques used to derive (10) give us

$$\frac{\partial L}{\partial w} = \frac{1}{w} \frac{R}{[C + (1 - t)wR]} \{C(\sigma - 1) + [(1 - t)A - (S - tY_b)]\} \tag{15}$$

This result is essentially the same as (10), with the wage rate deflated by the tax (and subsidy) rate, and with the term in the square brackets corresponding to $[A - S]$ in (10). The term $(1-t)A$ is net-of-tax nonwage income, and $(S - tY_B)$ is the portion of subsistence not covered by

[14] In analyzing the labor-leisure problem many authors implicitly assume that labor is the only source of income. As can be seen by comparing the second with the first (and third) row of diagrams, this may result in a serious error.

[15] An important omission in our analysis is the possibility that an individual may be able to forestall starvation by consuming part of his stock of wealth in addition to the flow of income resulting from it. This is, of course, only a short-run solution. A fuller treatment of this problem would require bringing time considerations explicitly into the analysis.

the guaranteed minimum income. As before, the sign of the term in the outer brackets determines the sign of $\partial L/\partial w$. For the case where $\sigma=1$, the supply curve is positively sloped if net nonlabor income exceeds the "net" subsistence term. It is not possible to determine a priori the effect of the tax plan on this final term, since the tax lowers net nonlabor income while the existence of the income floor weakens the force of the survival requirements.

Given, however, the notion of a minimum survival requirement, it would seem that if a guaranteed income has any meaning at all, it has to at least suffice for survival. We want, then, to examine the case where $tY_b \geq S$. The terms in square brackets in equation (15) must then be positive. The possible cases then reduce to those in the first row of Figure 1 (with trivial modifications in interpretation of the terms). The supply curve will always slope upwards initially, and may slope upwards throughout. Only when σ is sufficiently less than one is it possible for the labor supply to turn into a negatively sloping curve.

To understand the effects of the plan more completely, it is helpful to find the effect of a change in the tax rate on the supply of labor. This can be done by differentiating equations (13) and (14) partially with respect to the tax rate t. The result of these operations is shown in equation (16).

$$\frac{\partial L}{\partial t} = \frac{R[C(1-\sigma)+(S-Y_b)]}{(1-t)[C+(1-t)wR]} \tag{16}$$

Again the effect on the labor supply cannot be determined a priori, and it would take another series of nine figures to depict all of the possibilities. Notice that it is the break-even level of income, and not the floor (tY_b) on income, that is opposed to survival consumption S. Since the break-even level Y_b must be greater than the floor tY_b, and the floor in turn must exceed subsistence (see preceding paragraph), it is plausible that the break-even level will exceed subsistence. If this is the case, the effect of an increase in the tax (and subsidy) rate will be to decrease the labor supply (unless σ is sufficiently smaller than unity). Note also that at $Y=Y_b$ the tax is zero; consequently, for $Y=Y_b$ a change in the tax rate leads to a substitution effect but not to an income effect. As a final result, the partial effect of changes in the level of break-even income on labor supply can be found to be

$$\frac{\partial L}{\partial Y_b} = \frac{-tR}{[C+(1-t)wR]} \tag{17}$$

which is negative, given that $0<t<1$.

III. The Aggregate Supply Curve

The individual's demand for leisure is derived under the assumption that (in competition) the wage rate is an exogenously determined parameter; a change in the wage rate will lead to an income or wealth effect, in addition to the substitution effect. The central interest in this paper is with the uncompensated demand curve. So the demand for leisure in (8) and subsequently contains both a substitution and an income effect. It is well known that when considering the aggregate demand for a commodity, price is an endogenously determined parameter and, more importantly, that the net wealth effect will tend to zero. This recognition is one of the major contributions of general equilibrium analysis. Milton Friedman (1949) and subsequently Martin Bailey, in identically titled articles, "The Marshallian Demand Curve," both stress that in the aggregate, at a point in time, wealth effects tend to wash out due to the constraint imposed by the resource endowment of the economy. And in the absence of wealth effects, no Giffen goods are possible, and the aggregate demand curve for leisure, as for any other good, has to

slope down throughout.[16] But elsewhere in their writings, when drawing the supply curve of labor, both Friedman and Bailey allow for a negatively sloped portion of the curve. Friedman (1966) does not specify the level of aggregation, but Bailey (1962) clearly discusses the economy-wide supply curve of labor.

A possible explanation for such inconsistency is that empirical evidence strongly indicates a negative relation between the wage rate and the supply of labor. To the extent that this relation is observed in cross-sections, it is usually obtained for subgroups in truly partial equilibrium settings, and the evidence is not pertinent in determining the shape of the aggregate relation. As for time-series, the *ceteris paribus* is clearly violated. Comparisons are made between points in time for which the total productive capacity of the economy is not held constant. In other words, over time we observe not only the substitution due to an increase in real wages but also the effects of a net increase in real wealth. The wealth increase is not the result of the change in wage; if anything, it is the cause of the change in wage. Under these conditions, a negative relation between the quantity of labor supplied and the wage rate is easily understood, but this does not reflect on the slope of the supply curve at a point in time where wealth is constant.

This is not to imply that the aggregate supply curve of labor can never slope downwards or that (in the aggregate) Giffen goods can never be observed. These phenomena are not ruled out on a priori grounds, but may occur only under much more stringent conditions than usually specified. Suppose that the proceeds of a tax imposed on capital are used to subsidize labor. The relative price of labor will increase, and individuals supplying labor will experience positive wealth effects. On this account, the slope of the supply curve may become negative. On the other hand, individuals, in their capacity as owners of capital, will experience negative wealth effects and will demand less leisure and offer more labor services. For an individual whose capital holdings are exactly proportionate to the quantity of labor he supplies, the two income effects will cancel out. The other extreme is where all but one individual have no capital whatsoever while a single individual owns the entire capital stock of the economy. The wealthy owner will increase his labor supply as a result of the decline in his wealth by at most twenty-four hours a day. Since his contribution will be a minute fraction of the total, the aggregate supply curve can easily be negatively sloped. The actual situation is somewhere in between these two extremes and while the notion that the aggregate supply curve may slope down at a point in time is greatly weakened, it cannot be entirely rejected on a priori grounds.

IV. The Empirical Evidence

In *The Price of Leisure*, John Owen compiled *U.S.* time-series spanning the years 1901–61 for (among other things) the number of weekly hours of work and the corresponding real hourly wage. A number of important adjustments to the raw data make these series particularly useful for our purposes, especially in adjusting weekly hours for vacations and holidays and in excluding working students from the series from 1940 on.

The data, however, should be interpreted with great care. The coverage is for "private, non-agricultural wage and salary workers." If we assume, as seems reasonable, that the larger the asset holdings of an individual, the larger the chance that he will become self-employed, then the

[16] By the same token, it is not surprising that Stigler's search for Giffen goods is in vain. See George Stigler.

above classification of workers is biased towards individuals with low asset holdings. This has strong implications in interpreting the time-series. First, we saw that when the wage is parametric, the supply curve of individuals will vary substantially according to whether their level of assets is such that $A-S>0$ or $A-S<0$; this is evident in a comparison of the first and third rows of panels in Figure 1. In particular, as asset holdings increase, the relation $A-S<0$ will change to $A-S>0$, and at the same time, individuals will tend to drop out of the class of workers covered by the series. The individuals covered by the time-series, then, have particular asset holdings that will tend to bias the observed relation towards a negative slope.

Second, as noted above in the section on aggregation, to the extent that the change in wages is not accompanied by a shift in the transformation curve, the income effect on wage earners will be more or less matched by an income effect in the opposite direction on asset owners. But since the latter tend to be excluded from the sample, the effect on them is missed, and again the aggregative curve is biased towards a negative slope.[17]

In addition, during the period covered a dramatic shift occurred in productivity, and the observed increase in wage earners' incomes was not at the expense of asset holders. Consequently, the evidence afforded by the aggregative time-series corresponds more closely to that of the individual where wages are parametric and where increased wages mean a higher level of income than to the aggregative supply curve at a point in time where total income is constant.

The above discussion leads us to view the time-series as being obtained from a population for which asset holdings are not

[17] These two biases, however, are fortunate from the viewpoint of identifying the parameters of the underlying utility function.

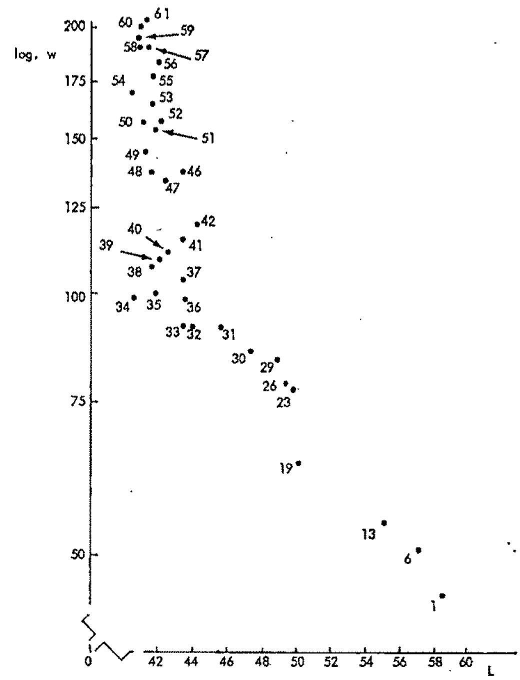

FIGURE 2

high (though perhaps rising) and to view the wage changes as parametric. So the data may narrow down the range of utility functions consistent with the evidence by shedding some light on the constanty of σ and on its value.

The data are plotted in Figure 2, where the horizontal axis measures hours worked per week and the vertical axis measures (on a logarithmic scale) the index of real wages. Individual points are identified according to their year. From 1901 to 1929 only selected points are available; from 1929 to 1961 the data are annual except for the omission of the war years, 1943–45.

The pattern that emerges conforms closely to Panel VIII of Figure 1, where $A-S<0$ and where $\sigma=1$.[18] During the first half of the period, from 1901 to the

[18] We should bear in mind that each of the diagrams in Figure 1 is drawn for a constant level of nonwage income. Since nonwage income is not held constant in the actual data, and since such income may be correlated with the level of wages, a possibility of a bias is present.

mid-1930's, real wages doubled, and weekly hours fell from 58 to about 42. During the second period, from the mid-1930's to 1961, real wages doubled again but hours remained virtually constant, particularly so if the war-related years are ignored. From 1948 to 1961, the range of variation of weekly hours is in the narrow band between 40.4 (1954) and 42 (1952) with no apparent trend.[19] This corresponds to the Cobb-Douglas utility function where the supply curve approaches asymptotically a positive number of hours.[20] Given that American wages in 1901 were substantially above those required for subsistence, the above evidence is insufficient to determine the minimum levels of consumption and rest.

Owen's data go only to 1961 and cover a very broad class of workers. During the 1960's real wages continued to increase, but weekly hours showed very little, if any, decline. Weekly hours for all production workers fell from 38.6 in 1961 to 37.0[21] (the coverage does not differ much from Owen's but the hours are unadjusted). This decline, however, is entirely due to a decline in hours in wholesale and retail trade (from 38.3 to 35.1); none of the other four subclasses, which include mining, construction, manufacturing and finance, showed any decline. Note that both 1961 and 1971 had high unemployment rates. The last decade, then, conforms to the pattern of the earlier period.

An interesting empirical implication (also useful for testing the conclusion that the utility function is Cobb-Douglas) is that as wages go up the divergence with respect to hours of work tends to disappear as between the capitalist and noncapitalist classes, i.e., between those with $A-S>0$ and those with $A-S<0$. Casual notions suggest that working habits of wealthier individuals in the United States do not differ much from those of less well-off individuals. Casual notions also suggest that the "leisure" class is quite prominent in poor countries where the real wages are low. These notions, if correct, tend to support the hypothesis that $\sigma=1$. Of course, a more careful and systematic analysis of the evidence is necessary to determine whether these casual notions are correct.

V. Some Further Comments

The attainable (survival) consumption set used in the preceding analysis was of a simple, "fixed coefficient" nature. A more complicated (and perhaps more realistic) formulation, allowing some substitution between the two commodities in meeting the requisites of survival, would in principle cause few difficulties in the formal theory.[22] However, the notion of net consumption (above survival) would then have little intuitive appeal, and it thus might be impossible to find a formulation of preferences yielding simple expressions like equations (8) and (9) for the slopes of the demand curves. The assumptions used do, however, seem to strike a reasonable balance between complicating the analysis severely and ignoring subsistence needs completely, since they allow simple types of preferences to generate a wide variety of types of demand (supply) curves.

Thus Hanoch verges on an error when he asserts (p. 639) that *CES* utility functions cannot produce backward bending

[19] The range will be further narrowed if we take account of cyclical fluctuations in unemployment, which are negatively correlated with the number of hours.

[20] It is interesting to note that since the end of the Second World War, weekly hours in Great Britain are also almost constant. There, however, the number is around 48 hours per week, The difference of about 7 hours per week between the two countries is an interesting puzzle.

[21] See the *Monthly Labor Review*.

[22] Provided that the new attainable set is convex. Otherwise, it may be impossible to even define convex preferences over the entire set of attainable consumption bundles. See Arrow and Gerard Debreu (1954) and Debreu.

supply curves and that a *C-D* utility function produces a vertical supply curve. His failure to take into account the wealth position and subsistence requirements of the individual has led him to use an unnecessarily complicated utility function to get his desired qualitative results. His illustration of a "conventional" supply curve, with $(A-S)$ implicitly set at zero, shows how unreasonable one can get if minimum consumption is not specified. Since his supply of labor becomes zero at all wage rates below $w=1$,[23] his consumer then would apparently prefer to starve to death rather than work and live at a wage less than 1.

In empirical studies of the supply of labor, the asset position of the individual is seldom taken into account. But a comparison of the first and third rows of Figure 1 clearly shows that even when assets are present we cannot simply add nonwage income as another variable in, say, a regression equation. Clearly, the coefficient for the wage rate depends on the level of nonwage income, and it even changes sign as assets pass through the level $A=S$. A simple relation allowing for no interaction effects, even if statistically "significant," gives average results for diverse groups of individuals, which in this case are entirely meaningless. More specifically, in a sample with assets distributed on both sides of the subsistence level, the estimated effect of the wage rate on the supply of labor will be biased toward zero. Given the model formulated above, however, the correct specification for the labor supply is shown by equations (A 10) and (A 11) of the Appendix. Equation (A 11), where it is assumed that $\sigma=1$, can be readily estimated by standard techniques; (A 10) poses more of a problem but could also be estimated if the hypothesis that $\sigma=1$ is not tenable.

[23] The units of w are not specified; thus, the entry point into the labor market is *not* invariant to the choice of units for the consumption good. His specific utility function in our notation is:

$$V(R, C) = R \exp\left[-\exp\left(-\frac{C}{R}\right)\right]$$

Appendix

To derive equation (10) it will be convenient to solve explicitly for the effects of asset changes on the demands for C and R. We can differentiate equations (4) and (6) totally to get

$$dC + w dR = dA + (D' - R)dw$$

$$f_1 dC + f_2 dR = dw$$

Letting dw be zero and recalling that at equilibrium $w=f$, we see that the partial effect of income on leisure is

$$\frac{\partial R}{\partial A} = f_1/(ff_1 - f_2) \tag{A 1}$$

Substituting this into (9) and rearranging, we have

$$\begin{aligned} \frac{\partial L}{\partial w} &= f_1/(ff_1-f_2)\left[\frac{1}{f_1}-(D'-R)\right] \\ &= \frac{1}{w} f_1/(ff_1 - f_2) \\ &\quad \cdot\left[\frac{f}{f_1}-(C+S-A)\right] \end{aligned} \tag{A 2}$$

where the budget constraint (4) has been used to substitute for $(D'-R)$ and we have again used $w=f$.

Assume now that the individual's preferences are homothetic in C and R, so the marginal rate of substitution is a function only of the ratio of consumption to leisure—that is, $f(C, R)$ is homogeneous of degree zero—so we may write

$$f(C, R) = h\left(\frac{C}{R}\right)$$

Then f_1 and f_2 can be written as

$$f_1 = \frac{h'}{R'}; \quad f_2 = -\frac{C}{R}\frac{h'}{R} \tag{A 3}$$

and we have

$$\text{(A 4)} \quad ff_1 - f_2 = \frac{h'}{R}\,\frac{(C + hR)}{R} > 0$$

by convexity. So it must be true that $h' > 0$. The income effects then become

$$\text{(A 5)} \quad \frac{\partial R}{\partial A} = \frac{R}{(C+wR)} \text{ and } \frac{\partial C}{\partial A} = \frac{C}{(C+wR)}$$

where the derivation of the latter parallels that for leisure.

The elasticity of substitution between the net quantities of consumption and leisure is defined as

$$\sigma = \frac{d\left(\frac{C}{R}\right) \Big/ \left(\frac{C}{R}\right)}{df/f}$$

where the differentials are for movements along an indifference curve. When preferences are homothetic this is simply

$$\text{(A 6)} \qquad \sigma = \frac{Rh}{Ch'}$$

and then we have

$$\text{(A 7)} \qquad \frac{f}{f_1} = \frac{Rh}{h'} = C\sigma$$

Equations (A5) and (A7) may then be substituted into (A2) to yield (A8).

$$\text{(A 8)} \quad \frac{\partial L}{\partial w} = \frac{1}{w}\,\frac{R}{(C + wR)} \cdot [C(\sigma - 1) + (A - S)]$$

Working in a parallel manner, equation (7) can be rewritten as

$$\text{(A 9)} \quad \frac{\partial C}{\partial w} = \frac{C}{(C + wR)}\,[R(\sigma - 1) + D']$$

It can also be shown that no weaker specifications on the individual's preferences will give these results.

The further assumption that the elasticity of substitution is a constant yields the explicit supply function

$$\text{(A 10)} \quad L = \frac{\left(\frac{\alpha}{1-\alpha}\right)^{\sigma} w^{\sigma} D' - (A - S)}{\left(\frac{\alpha}{1-\alpha}\right)^{\sigma} w^{\sigma} + w}$$

which reduces to

$$\text{(A 11)} \quad L = \alpha D' - (1 - \alpha)\left(\frac{A - S}{w}\right)$$

when $\sigma = 1$. This is the supply function that would be generated by a Cobb-Douglas type of utility function.

The Intrafamily Allocation of Time: The Value of the Housewives' Time

By REUBEN GRONAU*

In the new approach to consumption theory, the consumption activity is regarded as a production process in which time and goods are combined to produce utility. This new theory has revived interest in the family as the basic consumption unit.[1] While classical theory regarded "household" as synonymous with "individual," the new approach came to recognize that the members of a family each play a different role in the production of utility. Various authors[2] suggested that the classical dichotomy of "work in the market" versus "leisure" may serve as a good approximation of the role the husband plays in the production activity of the household but does gross injustice to the wife. To call the whole of the time spent by the wife outside the market sector "leisure" is to overlook the production activities she engages in at home. These activities are better termed work at home, and the wife's allocation of time should therefore be analyzed in terms of a three-way division of work in the market, work at home and leisure.

Recently, there have been some attempts to formalize the family decision-making process and to analyze the factors determining the intrafamily allocation of time and goods (Stuart Altman and Robert Barro, Reuben Gronau (1970b), Haim Ofek, James Smith). However, most of these attempts were based on a specific formulation of the form of the family utility function,[3] so that the validity of their results depends on the mathematical form used. A more serious limitation of most of these models (Altman and Barro, Ofek) is the failure to relate to or explain the salient feature of the intrafamily allocation of time—the fact that at each point of time over 60 percent of all married women are not actively engaged in market production and that during any given year not more than 50 percent participate in the labor force. The explicit or implicit assumption that the wife works in the market limits the relevance of these models to at most one-half of all families, but leaves unanswered questions relating to the remainder, where the wife's sole occupation is housewife.

This paper attempts a general formulation of the intrafamily allocation of time. The members of a family allocate their time according to their comparative advantage in the production of market and

* Hebrew University, Jerusalem. Parts of this paper are based on my study, "The Labor Force Participation of Israeli Women," carried out at the Maurice Falk Institute for Economic Research. I finished the paper while a postdoctoral fellow at the University of Chicago. I acknowledge the financial support of the Rockefeller Foundation through a grant to the University of Chicago for research on the Economics of Population and Family Decision Making. I benefitted from the suggestions of Gary Becker, Giora Hanoch, Ruth Klinov, David Levhari, Gregg Lewis, and Shlomo Yizhaki, and I am grateful to Randall Olson for his devoted research assistance.

[1] This new approach is associated with the work of Gary Becker (1965) and Kelvin Lancaster (1966) but can actually be dated back to Wesley Mitchell (1937). Among its recent exponents are Stuart Altman and Robert Barro (1970), Gilbert Ghez and Becker (1972), Gronau (1970), Michael Grossman (1972), Robert Michael (1973), Haim Ofek (1970), and others.

[2] Most notably Jacob Mincer (1962, 1963), and later Glen Cain (1966) and Marvin Kosters (1963).

[3] Ofek and Gronau (1970b) used a two-stage *CES* function while Altman and Barro used a Cobb-Douglas function.

home goods. Comparative advantage is in turn determined by their relative wage rates and their efficiency in the production of home goods. Husbands' wage rates as a rule exceed those of wives. Thus, we observe that, in general, husbands specialize in work in the market, while the wife specializes in the production of home goods. Very crudely, one can distinguish three situations of specialization: the case where the husband divides his time between work in the market and leisure and the wife works both in the market and at home, spending the rest of her time on leisure; the case where the wife drops out of the labor force; and the case where the husband enters the home production process. These three phases are reflected in a difference in the factors determining the value of the wife's time. The value placed by the family on the wife's time while she works in the market is, of course, determined by her own marginal wage rate. When she leaves the labor market this tie is severed, and the price of her time is determined, in the second case, by family income, and, in the third case, it is determined by her husband's wage rate.

The wife's decision whether to participate in the labor force can, therefore, be viewed in terms of the comparison between her value of time in the absence of market opportunities and her potential wage rate. The result of this comparison is recorded in the labor force statistics. These statistics yield themselves however to two different interpretations, based on the self-selection of working wives from a frequency distribution of their alternative price of time. According to the first, the wives who work are those who are the least productive in the home sector, i.e., those whose value of time is the lowest, and, hence, the mean price of time of housewives exceeds the average wage rate of working women. By the second interpretation, those who work are the women most fit for market work, i.e., those who have received the highest wage offers, and, hence, the mean price of time falls short of the average wage rate.

Using 1960 *U.S.* data it is found that under the first assumption, the housewives' average price of time exceeds the average wage of working women by less than 20 percent. Given the second assumption, the housewives' average price of time falls short of the average wage rate by about 20–30 percent. White women assign to their time a higher value than nonwhites. Only part of this difference may be explained by income differentials, the rest arising, seemingly, from differences in their age-education composition. Finally, it is found in the case of nonwhite women that the existence of a young child (less than three years old) raises his mother's price of time by about 6–8 percent. We could not, however, derive a similar estimate for white women.

I. The Intrafamily Allocation of Time

Let us consider for simplicity a household (family) consisting of two members: husband and wife. The household combines its members' leisure time with market and home goods to generate utility (U).

$$U = U(M, H, L_1, L_2) \tag{1}$$

The arguments of the utility function will be termed factors, where M denotes the amount of market goods, H the amount of home goods, L_1 the amount of the husband's leisure, L_2 the amount of leisure enjoyed by the wife.[4] Home goods, in turn, are produced with a combination of market inputs and time and can be produced by either husband or wife.

One of the things distinguishing a family

[4] This formulation ignores the effects that intrafamily distribution of goods may have on family welfare and assumes implicitly that work, whether in the market or in the nonmarket sector, carries no utility (or disutility).

from a single-person household is the exchange taking place within the family. Thus, the husband does not have to rely on his own talents to produce these goods (say, a meal) but can muster the services of his wife in exchange for say, his working in the market. Thus, $H = H_1 + H_2$ where

$$(2) \quad H_i = H_i(X_i, T_{Hi}), \qquad i = 1, 2$$

H_i being the amount of home goods produced by person i, and X_i and T_{Hi} being, respectively, the amount of market inputs and time used in the process. The family aims at maximizing its utility subject to the constraints it confronts. These constraints are of two kinds: (a) the budget constraint, and (b) the time constraint.

The family pools its pecuniary resources. Adopting a one-period model, the budget constraint states that expenditure on market goods and inputs cannot exceed the family income (I).

$$(3) \quad P_M M + P_X X = W_1 T_{M_1} + W_2 T_{M_2} + V = I$$

where W_i denotes the wage rate of member i, T_{Mi} the amount of time he spends working in the market, V other sources of income besides earnings, P_M and P_X the price of market goods (M) and inputs (X), respectively, and $X = X_1 + X_2$.

The family faces two separate time constraints stating that the amount of time spent by person i on work in the market, work at home, and leisure cannot exceed the total amount of time available (T_0)

$$(4) \quad T_{Mi} + T_{Hi} + L_i = T_0 \qquad i = 1, 2$$

The maximization of the utility function (1) subject to the production function for home goods (2), and the budget and time constraints ((3) and (4), respectively), yields the family members' optimum allocation of time and the family's optimum allocation of expenditure between market goods and market inputs.

This optimum solution depends on the specific nature of the utility function, the home goods production functions and the family members' wage rates and other sources of income. Let us assume, for simplicity, that the production of home goods calls for the combination of time and market inputs in fixed proportions.[5] Moreover, let us assume that these functions differ between husband and wife:

$$(5) \quad H_i = \min\left(\frac{X_i}{\gamma_i}, \frac{T_{Hi}}{\delta_i}\right) \qquad i = 1, 2$$

$1/\gamma_i$ and $1/\delta_i$ being, respectively, the marginal products of market inputs and time in the production of home goods. Given this assumption, inputs vary proportionately with the amount of home goods produced

$$(6) \quad \begin{aligned} X_i &= \gamma_i H_i \\ T_{Hi} &= \delta_i H_i \qquad i = 1, 2 \end{aligned}$$

The marginal cost of producing one unit of home goods by person $i(\Pi_i)$ is

$$(7) \quad \Pi_i = \gamma_i P_X + \delta_i W_i^* \qquad i = 1, 2$$

where W_i^* is the value placed on the time of person i.

If we assume that the values placed on the husband's and wife's time are constant (though not identical) and do not vary with amount of home goods produced,[6] and given our previous assumption concerning the constancy of δ_i and γ_i the marginal costs of producing home goods are constant and differ, in general, between husband and wife. The family will turn for its supply of home goods to the cheaper of the two producers.

[5] This strong assumption could be replaced by the weaker assumption that the production function of home goods is homogeneous of degree $t \geq 1$ without affecting the major conclusions of the model but at the cost of greatly complicating the computations.

[6] This assumption is removed later in this section.

Case I: Both Members of the Family Participate in the Labor Force

If both members of the family participate in the labor force, the value of their time equals their wage rate ($W_i^* = W_i$).[7] Their marginal costs of producing home goods are therefore

$$\Pi_i = \gamma_i P_X + \delta_i W_i \qquad i = 1, 2 \tag{8}$$

The ith person's marginal costs of producing home goods depend on his marginal productivity (γ_i and δ_i) and his wage rate. Since in general the husband's exceeds the wife's wage rate the price charged by the husband for home goods exceeds that charged by the wife unless this difference in wages is offset by differences in efficiency. Consequently, all home goods are going to be produced by the wife, while her husband divides his time between work in the market and leisure (i.e., $T_{H_1} = 0$).

In this case, one can incorporate both time constraints (4) into the budget constraint (3) to obtain one ultimate constraint

$$\begin{aligned} I &= P_M M + P_X X_2 \\ &= W_1(T_0 - L_1) + W_2(T_0 - T_{H_2} - L_2) + V \end{aligned} \tag{9}$$

Inserting the values of X_2 and T_{H_2} in terms of the output of home goods into the equation, this constraint can be written

$$\begin{aligned} P_M M + \Pi H + W_1 L_1 + W_2 L_2 \\ = (W_1 + W_2) T_0 + V = I^* \end{aligned} \tag{10}$$

where $\Pi = \gamma_2 P_X + \delta_2 W_2$ is the price of home goods, and I^* is the family's "full income," i.e., the income the family could have earned had it devoted all its time to work in the market.

The maximization of utility subject to the ultimate constraint (10) yields the familiar optimum conditions

$$\begin{aligned} u_M &= \lambda P_M \\ u_H &= \lambda \Pi \\ u_{L_1} &= \lambda W_1 \end{aligned} \tag{11}$$

and

$$u_{L_2} = \lambda W_2$$

where $u_Z(Z{:}M, H, L_1, L_2)$ denotes the marginal utility of factor Z, and λ is the marginal utility of income.

Given these necessary conditions one can generate the demand elasticities for market goods, home goods, and leisure. Of particular interest are the demand elasticities with respect to the husband's and wife's wage rates. The demand elasticity for factor $Z(Z{:}M, H, L_1$ or $L_2)$ with respect to the husband's wage rate (ϵ_{ZW_1}) is

$$\epsilon_{ZW_1} = \frac{W_1 L_1}{I^*} \sigma_{L_1 Z} + \frac{W_1 T_{M_1}}{I^*} \epsilon_{ZI^*} \tag{12}$$

where $\sigma_{L_1 Z}$ denotes the Allen partial elasticity of substitution between factor Z and the husband's leisure, and ϵ_{ZI^*} denotes the "full income" elasticity of demand.[8] Specifically, the demand elasticity for the husband's leisure with respect to his wage rate is shown by equation (13).

[7] Recall our assumption that work does not carry any utility (see fn. 4). Without this assumption one has to adjust the value of time for the money equivalent of the marginal utility (or disutility) of work (see Bruce Johnson (1966) and Gronau (1970a)).

[8] The full income elasticity exceeds the income elasticity of demand

$$\epsilon_{ZI^*} = \frac{I^*}{I} \epsilon_{ZI} > \epsilon_{ZI},$$

and equation (12) can also be written

$$\epsilon_{ZW_1} = \frac{W_1 L_1}{I^*} \sigma_{L_1 Z} + \frac{W_1 T_{M_1}}{I} \epsilon_{ZI}$$

When the utility function is linear homogeneous $\epsilon_{ZI^*} = 1$ and

$$\epsilon_{ZW_1} = \frac{W_1 L_1}{I^*} \sigma_{L_1 Z} + \frac{W_1 T_{M_1}}{I^*}$$

$$(13)\qquad \epsilon_{L_1W_1} = \frac{W_1L_1}{I^*}\sigma_{L_1W_1} + \frac{W_1T_{M_1}}{I^*}\epsilon_{L_1I^*}$$

The husband's elasticity of supply of working time is therefore

$$(14)\qquad \epsilon_{T_{M_2}W_1} = -\frac{L_1}{T_{M_1}}\epsilon_{L_1W_1}$$

$$= -\left(\frac{W_1L_1}{I^*}\frac{L_1}{T_{M_1}}\sigma_{L_1L_1} + \epsilon_{L_1I^*}\right)$$

Since $\sigma_{L_1L_1}$ is always negative and $\epsilon_{L_1I^*}$ can be safely assumed to be positive, we encounter the familiar result that the slope of the labor supply curve depends on the relative magnitudes of the elasticity of substitution and the full income elasticity of leisure.[9]

Similarly, the cross elasticities of demand for home goods and the wife's leisure with respect to the husband's wage rate are

$$(15)\qquad \epsilon_{HW_1} = \frac{W_1L_1}{I^*}\sigma_{L_1H} + \frac{W_1T_M}{I^*}\epsilon_{HI^*}$$

$$\epsilon_{L_2W_1} = \frac{W_1L_1}{I^*}\sigma_{L_1L_2} + \frac{W_1T_{M_1}}{I^*}\epsilon_{L_2I^*}$$

The elasticity of demand for the wife's working time at home with respect to her husband's wage rate ($\epsilon_{T_{H_2}W_1}$) equals the demand elasticity for home goods with respect to $W_1(\epsilon_{HW_1})$. If home goods and the wife's leisure are competitive with the husband's leisure (i.e., if $\sigma_{L_1L_2}$, $\sigma_{L_1H}>0$), an increase in the husband's wage rate will be accompanied by an increase in the amount of time the wife spends at home and, consequently, by a decline in the amount of time she devotes to the market sector.[10] This is seen in equation (16).

$$(16)\qquad \epsilon_{T_{M_2}W_1} = -\left\{\frac{W_1L_1}{I^*}\left(\frac{L_2}{T_{M_2}}\sigma_{L_1L_2} + \frac{T_{H_2}}{T_{M_2}}\sigma_{L_1H}\right) + \frac{W_1T_{M_1}}{I^*}\left(\frac{L_2}{T_{M_2}}\epsilon_{L_2I^*} + \frac{T_{H_2}}{T_{M_2}}\epsilon_{HI^*}\right)\right\}$$

An increase in the wife's wage rate increases both the price of her leisure and the price of home goods, the increase in the latter being a function of the share of the cost of time in the total production cost of home goods. The demand elasticity of factor $Z(Z\!:\!M$, H, L_1, or $L_2)$ with respect to the wife's wage rate reflects the substitution elasticity of factor Z for both the wife's leisure and home goods, as well as the full income elasticity of this factor

$$(17)\qquad \epsilon_{ZW_2} = \frac{W_2L_2}{I^*}\sigma_{L_2Z} + \frac{W_2T_{H_2}}{I^*}\sigma_{HZ} + \frac{W_2T_{M_2}}{I^*}\epsilon_{ZI^*}$$

Under the previous assumption that the husband's leisure is competitive with both home goods and the wife's leisure one would expect the husband's leisure to increase, and hence his supply of labor to decrease, as his wife's wage rate increases. This is seen in equation (18).

[9] When the utility function is linear homogeneous the necessary condition for the backward bending supply curve of labor is

$$|\sigma_{L_1L_1}| > \frac{T_{M_1}}{L_1} = \frac{T_{M_1}}{T_0 - T_{M_1}}$$

[10] This conclusion holds even if the husband's and wife's leisure are complementary factors and $\sigma_{L_1L_2}<0$ so long as the elasticity of substitution between the husband's leisure and home goods (σ_{L_1H}) is positive and sufficiently large.

$$(18)\quad \epsilon_{TM_1W_2} = -\frac{L_1}{T_{M_1}}\left(\frac{W_2L_2}{I^*}\sigma_{L_1L_2} + \frac{W_2T_{H_2}}{I^*}\sigma_{L_1H} + \frac{W_2T_{M_2}}{I^*}\epsilon_{L_1I^*}\right)$$

However, it can be shown that, in general, the wife's supply of labor is more sensitive to changes in her husband's wage rate than her husband's supply of labor is to changes in her wage rate.[11]

The elasticity of the wife's supply of labor with respect to her own wage rate depends on the family's demand for her leisure and for home goods. These elasticities are

$$(19)\quad \epsilon_{L_2W_2} = \frac{W_2L_2}{I^*}\sigma_{L_2L_2} + \frac{W_2T_{H_2}}{I^*}\sigma_{HL_2} + \frac{W_2T_{M_2}}{I^*}\epsilon_{L_2I^*}$$

and

$$\epsilon_{HW_2} = \frac{W_2L_2}{I^*}\sigma_{HL_2} + \frac{W_2T_{H_2}}{I^*}\sigma_{HH} + \frac{W_2T_{M_2}}{I^*}\epsilon_{HI^*}$$

The sign of these elasticities is indeterminate since the income and substitution effects tend to have opposite effects on the quantity of leisure demanded.[12] Given the income elasticities ($\epsilon_{L_2I^*}$ and ϵ_{HI^*}) and the substitution elasticities ($\sigma_{L_2L_2}$, σ_{HH}, and σ_{HL_2}), the demand elasticities ($\epsilon_{L_2W_2}$ and ϵ_{HW_2}) depend on the distribution of the wife's time between market and nonmarket activities. The smaller amount of time the wife spends in the market, the smaller the income effect, and since

$$(20)\quad \epsilon_{T_{M_2}W_2} = -\left(\frac{L_2}{T_{M_2}}\epsilon_{L_2W_2} + \frac{T_{H2}}{T_{M_2}}\epsilon_{HW_2}\right)$$

the greater the tendency of her supply of labor to be positively sloped. Furthermore, if the income elasticities of all factors are the same (specifically, if $\epsilon_{L_1I^*} = \epsilon_{L_2I^*} = \epsilon_{HI^*}$) one would, from a comparison of (20), (19), and (14), expect the wife's labor supply curve to have less tendency to bend backwards than her husband's, since the wife's earnings constitute a smaller share of full income than the husband's. Put differently, if the wife's labor supply curve bends backwards it will do so only at a point (i.e., number of hours) which is to the right of the bending point of her husband's supply curve.

Case II: Only the Husband Participates in the Labor Market

An increase in family income, whether as a result of an increase in the husband's wage rate (W_1) or in other sources of income (V), is accompanied by an increase

[11] Comparing (16) and (18) we get

$$\epsilon_{T_{M_2}W_1} - \epsilon_{T_{M_1}W_2} = \frac{1}{I^*}\left\{\frac{L_1(W_1T_{M_1} - W_2T_{M_2})}{T_{M_1}T_{M_2}}(L_2\sigma_{L_1L_2} + T_{H_2}\sigma_{L_1H}) + \left(\frac{W_1T_{M_1}}{T_{M_2}}(L_2\epsilon_{L_2I^*} + T_{H_2}\epsilon_{HI^*}) - \left(\frac{W_2T_{M_2}}{T_{M_1}}L_1\epsilon_{L_1I^*}\right)\right\}$$

If the full income elasticities $\epsilon_{L_1I^*}, \epsilon_{L_2I^*}$ and ϵ_{HI^*} are about equal, $\epsilon_{T_{M2}W_1} > \epsilon_{T_{M1}W_2}$, since the husband spends more time than his wife in the market and earns more than she does.

[12] Assuming home goods and the wife's leisure to be normal (i.e., not inferior) inputs and σ_{ML_1}, σ_{MH}, $\sigma_{L_1L_2}$, $\sigma_{L_1H} > 0$.

in the demand for both wife's leisure and home goods. Eventually, the wife drops out of the labor market altogether, dividing her time exclusively between work at home and leisure. The wife's exit from the labor market severs the link between the value of her time and her potential wage rate (i.e., the wage she could have earned had she stayed in the labor force). The value placed by the family on the wife's time depends on the value of the marginal product of her labor inputs in the production of home goods. The mere fact that the wife prefers not to work in the market indicates that the value of her time exceeds her potential wage rate.

Formally, when the wife is not working in the market one cannot treat identically the two separate time constraints confronting the family, i.e., one cannot incorporate both constraints in the ultimate budget constraint. The family's budget is unaffected by the wife's allocation of time between work at home and leisure. If we still maintain that the husband does not work at home, one can write the budget constraint as

$$P_M M + P_X X_2 = W_1 T_{M_1} + V = W_1(T_0 - L_1) + V \tag{21}$$

or alternatively as

$$P_M M + P_X \gamma_2 H + W_1 L_1 = W_1 T_0 + V \tag{22}$$

The family, however, faces an additional constraint—the wife's time constraint, stating that the time used by the wife in the production of home goods plus her leisure time cannot exceed total time available.

$$T_{H_2} + L_2 = \delta_2 H + L_2 = T_0 \tag{23}$$

The maximization of utility therefore takes place under two separate constraints: the budget constraint (22) and the wife's time constraint (23).

The optimum conditions look familiar

$$\begin{aligned} u_M &= \lambda P_M \\ u_H &= \lambda \Pi^* \\ u_{L_1} &= \lambda W_1 \end{aligned} \tag{24}$$

and

$$u_{L_2} = \lambda W_2^*$$

where $\Pi^* = \lambda_2 P_X + \delta_2 W_2^*$. However, in this case, the value W_2^* placed on the wife's time, and, consequently, the price of home goods Π^* is not exogeneously given, but rather determined by the maximization process. A change in the parameters (P_M, P_X, W_1, and V) changes both the optimum solution and the price placed by the family on the wife's time and home goods.

For example, an increase in the family's other sources of income (V) would, in the absence of the wife's time constraint, result in an increase of all the four components of the utility function (assuming none of the four is an inferior input). However, given the time constraint the wife cannot simultaneously increase both her leisure and the time she spends in producing home goods. The increase in the demand for the wife's time results in an increase in the price placed on this time. The increase in income is, therefore, accompanied by a substitution of the husband's leisure and market goods for the wife's leisure and home goods.[13] The leisure of husbands whose wives do not work should, therefore, be more sensitive to changes in income than the leisure of husbands whose wives work in the market. Put differently, the tendency for the husband's supply of labor to bend backwards should be more prevalent among husbands

[13] The proof is included in an unpublished Appendix. The result that the price assigned to the housewife's time increases with family income is a general one, and holds even if one does not distinguish between the wife's leisure and her work at home. The distinction is, however, crucial if one wants to explain the different participation patterns of husbands and wives.

of nonworking wives than among husbands of working wives.

As for the wife, an increase in income results in an increase in the value of her time and an increase in the price of both her leisure and home goods, the increase in the latter being a function of the share of the cost of time in the total production costs of home goods. The demand for the wife's leisure and time inputs in the production of home goods is, therefore, affected by two contradictory forces: the income effect and the substitution effect. Since the total time available for the two activities remains constant, the increase in the price of time must be sufficiently large for the substitution effect of one of these factors to outweigh its income effect. Which of these factors, the wife's leisure or her working time at home, will decline depends on the part time plays in the production of home goods, the income elasticities of the two factors and the substitution elasticities between these factors and market goods and the husband's leisure σ_{MH}, σ_{ML_2}, σ_{HL_1}, and $\sigma_{L_2L_1}$.[14]

Finally, if the husband's wage rate W_1 and other sources of income are sufficiently large, the value placed on the wife's time becomes so large as to make husband-produced and wife-produced home goods equally costly

$$(25)\quad \Pi_1=\gamma_1 P_X+\delta_1 W_1=\gamma_2 P_X+\delta_2 W_2^*=\Pi_2^*$$

In this case the husband is called upon to help his wife at home. The husband divides his time between work in the market, work at home, and leisure, while his wife divides her time between work at home and leisure. The wife's value of time is pegged to her husband's wage rate.

$$(26)\quad W_2^*=\left(\frac{\gamma_1-\gamma_2}{\delta_2}\right)P_X+\left(\frac{\delta_1}{\delta_2}\right)W_1$$

[14] The proof is included in an unpublished Appendix.

When husband and wife are equally efficient in the use of market inputs ($\gamma_1=\gamma_2$) the wife's value of time is proportionate to the husband's. The wife's price of time will equal the husband's wage rate if both husband and wife share the same production function.

In this case an increase in other sources of income (V), husband's wage rate remaining constant, does not change the relative prices of goods and leisure. Thus, the increase in V should result in an increase in the demand of all factors. Both husband's and wife's leisure are expected to increase. Likewise, one expects the production of home goods to expand, the husband taking over some of the work given up by his wife. The increase in the husband's leisure and his work at home result in a decline of the amount of work supplied in the market.

An increase in the husband's wage rate raises the price of both his and his wife's leisure and the price of home goods relative to the price of market goods. The substitution effect tends to increase the husband's work in the market while the income effect works in the opposite direction. Similarly, one cannot predict the effect of an increase in the husband's wage rate on the wife's allocation of time. It depends on the relative change of the price of the wife's leisure versus the price of home goods and on the income and substitution elasticities of these two factors.

II. The Value of the Housewives' Time

An empirical estimation of the demand for leisure and the supply of work at home calls for detailed data concerning the time budgets of the various family members. The existing published data are too crude to provide conclusive results. In the absence of data on the nonmarket sector one has to make inferences about the decision-making process of the family from its revealed preferences with respect to work in

the market. This subject has been investigated in the family context, with somewhat mixed results.[15] However, one implication of our model that has been entirely overlooked is the implication of labor force participation on the value of housewives' time.

Over 60 percent of married women in the United States are classified as full-time housewives (William Bowen and T. A. Finegan, p. 88). Thus, the wage rate serves only as a very crude indication of the value of time for more than one-quarter of the adult population. Given the importance of the price of time as a determinant of housewives' purchasing, travelling, and recreation habits it is of the utmost importance to get some better estimate of the value of time for this population group. Such an estimate can be generated from the observed data on labor force participation.

One of the implications of the preceding section states that while the value of time of working women equals their wage rate, the value placed on the time of housewives exceeds their potential wage rate and increases with family income. The wife's decision to enter the labor market can therefore serve as an indication that in the absence of market opportunities her value of time would have fallen short of her current wage rate. Similarly, the wife's decision to refrain from entering the labor force indicates that her value of time exceeds her potential wage rate.

The rate of labor force participation depends on the joint distribution of the potential wage rate and the wives' price of time in the absence of market opportunities. Formally, let $f(W, W^*)$ be the joint density function of the potential wage W and the price of time W^*, then the participation rate equals

$$(27)\quad P = \text{Prob}\,(W > W^*) = \int_{-\infty}^{\infty}\int_{W^*}^{\infty} f(W, W^*)dWdW^*$$

The average wage of working women and the housewives' average price of time are means of truncated distributions. The average wage $\overline{W}$ equals the expected value of W, where W exceeds W^*,

$$(28)\quad \overline{W} = E(W \mid W > W^*) = \frac{1}{P}\int_{-\infty}^{\infty}\int_{W^*}^{\infty} Wf(W, W^*)dWdW^*$$

and the housewives' average price of time $\overline{W}^*$ is the conditional expectation of W^* where W^* exceeds W.

$$(29)\quad \overline{W}^* = E(W^* \mid W^* > W) = \frac{1}{1-P}\int_{-\infty}^{\infty}\int_{W}^{\infty} W^*f(W, W^*)dW^*dW$$

A prerequisite for the estimation of $\overline{W}^*$ (and the factors determining labor force participation) is the knowledge of the shape and parameters of $f(W, W^*)$.[16]

To estimate $f(W, W^*)$ one has to rely on knowledge of the truncated wage distribution $g(W \mid W > W^*)$ and the portion this distribution constitutes of the total wage offer distribution, i.e., the participation rate $P = \text{Prob}\,(W > W^*)$. In general one does not possess any information with regard to $g(W \mid W > W^*)$ beyond the knowledge of its mean. Thus, one has to replace the missing information by a set of assumptions. I shall assume that W and W^* are independently distributed and that their joint distribution is bivariate normal

[15] Kosters estimated the supply of hours of work of men aged 50–64, but was unable to produce a positive compensated wage rate elasticity. Cain came up with estimates of elasticities which have the right sign. However, a recent paper by Yoram Ben-Porath casts doubts on the validity of Cain's interpretation.

[16] For a more detailed analysis of the problems involved in the estimation of the determinants of labor force participation see Ben-Porath and, in particular, Gregg Lewis.

$$(30)\quad f(W, W^*) = \frac{1}{2\Pi\sigma_W\sigma_{W^*}} \exp\left\{-\frac{1}{2}\left(\frac{W-\mu_W}{\sigma_W}\right)^2 + \left(\frac{W^*-\mu_{W^*}}{\sigma_{W^*}}\right)^2\right\} = \frac{1}{2\Pi\sigma_W\sigma_{W^*}} \cdot \exp\left\{-\frac{1}{2}(x^2+y^2)\right\}$$

where μ_W and μ_{W^*} are the mean values, and σ_W and σ_{W^*} are the standard deviations of the marginal distributions of W and W^*, respectively, and where $x=(W-\mu_W)/\sigma_W$ and $y=(W^*-\mu_{W^*})/\sigma_{W^*}$ are standardized normal variables. Of the two assumptions, normality and independence, the latter is clearly the more controversial since it asserts that none of the factors determining W (for example, education, age, natural ability) affects W^*, and vice versa. This assumption is, therefore, adopted with mixed feelings, being crucial to the estimation procedure.

Let it be assumed that the mean wage rate μ_W is a sole function of age and education and that the mean price of time μ_{W^*} depends solely on the family's income. The rate of labor force participation within a given age-education-income group equals

$$(31)\quad P = \text{Prob}\,(W=\mu_W+x\sigma_W>\mu_{W^*}+y\sigma_{W^*} = W^*) = \text{Prob}\,(x>A+By=y^*) = \frac{1}{2\Pi}\int_{-\infty}^{\infty}\int_{y^*}^{\infty}\exp\left\{-\tfrac{1}{2}(x^2+y^2)\right\}dxdy$$

where $A=(\mu_{W^*}-\mu_W)/\sigma_W$ and $B=\sigma_{W^*}/\sigma_W$. The average wage rate of working women equals

$$(32)\quad \overline{W} = \mu_W + \bar{x}\sigma_W$$

where[17]

[17] See the mathematical appendix of Gronau (1973).

$$(33)\quad \bar{x} = E(x \mid x > y^*) = \frac{1}{2\Pi P}\int_{-\infty}^{\infty}\int_{y^*}^{\infty} x \exp\left\{-\frac{1}{2}(x^2+y^2)\right\}dxdy = \frac{1}{P}\left(2\Pi\frac{\sigma_W^2+\sigma_{W^*}^2}{\sigma_W}\right)^{-1/2} \cdot \exp\left\{-\frac{1}{2}\frac{(\mu_{W^*}-\mu_W)^2}{\sigma_W^2+\sigma_{W^*}^2}\right\}$$

The knowledge of P and $\overline{W}$ is insufficient for the estimation of the four parameters of $f(W, W^*)$, namely μ_W, μ_{W^*}, σ_W and σ_{W^*}. To estimate these parameters we have to adopt two alternative extreme assumptions:

a) $\sigma_W=0$ and σ_{W^*} is insensitive to income

and b) $\sigma_{W^*}=0$ and σ_W is independent of age and education.

If it is assumed that all women in a given age-education group anticipate the same wage rate μ_W (i.e., $\sigma_W=0$), differences in participation behavior of women sharing the same market characteristics are explained in terms of differences in their price of time (see Figure 1). The labor force participation rate within an age-education-income group equals

$$(34)\quad P = \text{Prob}\,(W^*<\mu_W) = \text{Prob}\left(y=\frac{W^*-\mu_{W^*}}{\sigma_{W^*}}<\frac{\mu_W-\mu_{W^*}}{\sigma_{W^*}} = -\frac{A}{B}=Z\right)$$

Moreover, since $\sigma_W=0$, the average wage rate of working women equals the mean value of the wage offer distribution $\overline{W}=\mu_W$. Thus

$$(35)\quad Z = -\frac{A}{B} = \frac{\mu_W-\mu_{W^*}}{\sigma_{W^*}} = \frac{\overline{W}-\mu_{W^*}}{\sigma_{W^*}}$$

or alternatively

$$(36)\quad \overline{W} = \mu_{W^*} + Z\sigma_{W^*}$$

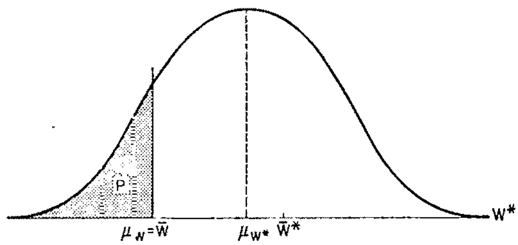

FIGURE 1

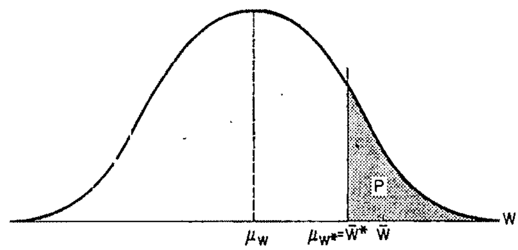

FIGURE 2

Observing that in income group i, P_{ij} percent of the women belonging to potential wage group j (i.e., age-education group j) participate in the labor force, one can (using the tables of the normal distribution) generate the values of Z_{ij} satisfying Prob $(Z<Z_{ij})=P_{ij}$. Given a sufficient number of potential wage groups one can estimate within each income group i

$$(37) \qquad \overline{W}_{ij} = a_i + b_i Z_{ij}$$

the constant term a_i serving as the estimate of the mean value of time μ_{W^*i} in this income group and the regression coefficient b_i serving as an estimate of the standard deviation σ_{W^*i}.

Alternatively, one can assume that differences in participation behavior originate in differences in wage offers, i.e., the standard deviation of the value of time distribution within a given income group equals zero ($\sigma_{W^*}=0$, see Figure 2). The rate of participation within a given age-education-income group is

$$(38) \qquad P = \text{Prob}\,(W > \mu_{W^*}) = \text{Prob}\left(x = \frac{W-\mu_W}{\sigma_W} > \frac{\mu_{W^*}-\mu_W}{\sigma_W} = A\right)$$

By equations (32) and (33) the average wage of working women is $\overline{W}=\mu_W+\bar{x}\sigma_W$ where

$$(39) \qquad \bar{x} = E(x \mid x > y^* = A) = \frac{1}{P\sqrt{2\Pi}}\int_A^\infty x \exp\left(-\tfrac{1}{2}x^2\right)dx = \frac{1}{P\sqrt{2\Pi}}\exp\left(-\tfrac{1}{2}A^2\right)$$

since $B=0$

Given the value of P_{ij}, one can generate the value of A_{ij} and compute the value of $\bar{x}_{ij}$. Since $\mu_W=\mu_{W^*}-A\sigma_W$

$$(40) \qquad \overline{W}_{\cdot j} = \mu_{Wj} + \bar{x}_{ij}\sigma_{Wj} = \mu_{W^*i} + (\bar{x}_{ij} - A_{ij})\sigma_{Wj} = \mu_{W^*} + Z^*_{ij}\sigma_{Wj}$$

Assuming that the standard deviation of the wage offer distribution does not vary among potential wage groups, one can estimate within each income group

$$(41) \qquad \overline{W}_{ij} = a_i + bZ^*_{ij}$$

Again, the constant is an estimate of the mean value of time μ_{W^*i} and the regression coefficient b is an estimate of the standard deviation of the wage offer distribution σ_W.

If one assumes that all women in a given income group share the same price of time ($\sigma_{W^*}=0$), $\overline{W}^*$ equals μ_{W^*} and equation (41) can be used to estimate the housewives' average price of time. If, however, one adopts the other assumption, i.e., that women belonging to the same income-age-education group have identical wage expectations but may differ in the price assigned to their time, $\overline{W}^*$ exceeds μ_{W^*}

$$\overline{W}^* = \mu_{W^*} + \bar{y}\sigma_{W^*} \geq \mu_{W^*} \tag{42}$$

since[18]

$$\bar{y} = E(y/y^* > x) \tag{43}$$
$$= \frac{1}{(1-P)\sqrt{2\Pi}} \exp\left(-\tfrac{1}{2}Z^2\right) > 0$$

One therefore has to compute $\bar{y}$, and using the estimates of μ_{W^*} and σ_{W^*} derived from equation (37) one can obtain an estimate of the housewives' average price of time.

It is worth noting the difference between our two assumptions. According to the first assumption ($\sigma_W = 0$), women who work are those who have the lowest price of time, i.e., are the least productive at home while by the second assumption ($\sigma_{W^*} = 0$), women who work are those who have received the highest wage offers, i.e., are the most productive in the market. This difference carries over to the relationship between the housewives' average value of time and the average market wage rate. According to the first assumption, one expects the housewives' average value of time to exceed the average wage rate, $\overline{W}^* = E(W^* | W^* > \mu_W = \overline{W}) \geq \overline{W}$. By the second assumption $\overline{W}^*$ falls short of $\overline{W}$, i.e. $\overline{W} = E(W | W > \mu_{W^*} = \overline{W}^*) \geq \overline{W}^*$. Actually, it can be shown that these estimates yield extreme limits for the mean value of time.[19]

Finally, if the size of the sample does not allow a very detailed classification of potential wage groups, the number of observations might be too small to allow reliable estimates of equations (37) and (41). In this case the relationship between the mean value of time μ_{W^*} and income I (i.e., $\mu_{W^*i} = g(I_i)$) must be prespecified.

[18] See the Appendix of Gronau (1973).

[19] See the Appendix of Gronau (1973). I have not been able to prove that the first estimate yields an upper limit of μ_{W^*}.

Thus, if, for example, one assumes that there exists a linear relationship

$$\mu_{W^*i} = \alpha_0 + \alpha_1 I_i \tag{44}$$

one can estimate

$$\overline{W}_{ij} = a + b_1 I_i + b_2 Z_{ij} \tag{45}$$
$$\overline{W}_{ij} = a + b_1 I_i + b_3 Z_{ij}^*$$

where $a = \text{est}(\alpha_0)$, $b_1 = \text{est}(\beta_1)$, $b_2 = \text{est}(\sigma_{W^*})$, and $b_3 = \text{est}(\sigma_W)$

IV. The Results

To estimate the value of time of *U.S.* housewives, I used the 1960 Census 1/1000 sample. To isolate the effect of other adults (besides the husband and the wife) on home production and the housewife's value of time I focused on primary families in households without nonrelatives. The sample was restricted to urban white (with no Spanish surname) and Negro married women, spouse present, and consisted of 26,530 observations.

These observations were subclassified according to the woman's race (white, Negro), age (less than 30, 30–49, 40–49, 50+), education (elementary school, high school, college and graduate studies), annual family income when the wife's earnings are excluded (income less than \$2,000, \$2,000–\$2,999, \$3,000–\$3,999, . . . , \$9,000–\$9,999, \$10,000–\$14,999, \$15,000–\$19,999, and \$20,000+) and the existence or nonexistence of children less than three years old. This classification yielded 768 cells (=2x4x4x12x2).

For each cell, I computed the rate of labor force participation (i.e., the percentage of women working or looking actively for work in the week preceding the census), the average income and the average wage of working women. The participation measure reflects the wife's work decision with respect to one specific week

TABLE 1—EDUCATION, AGE, INCOME, AND WAGE DISTRIBUTIONS OF URBAN MARRIED WOMEN BY RACE AND EXISTENCE OF YOUNG CHILD

	Whites			Nonwhites		
	Total[a]	No Young Child[d]	One Young Child	Total[a]	No Young Child	One Young Child
Number in Sample	24,462	19,244	4,079	2,068	1,547	339
Educational Distribution[c]						
Elementary School	24.5	28.1	10.8	42.8	47.7	27.7
High School	58.3	55.4	68.7	48.8	44.2	61.4
College	16.0	15.1	19.3	7.3	7.0	9.4
Graduate Education	1.3	1.3	1.3	1.1	1.0	1.5
Age Distribution[c]						
<30	25.9	14.2	65.9	30.6	17.8	63.1
30–39	27.0	26.5	31.1	29.0	29.6	30.7
40–49	22.1	27.4	2.9	20.6	26.1	5.6
50+	25.1	31.8	0.1	19.9	26.4	0.6
Average Income[b]						
Total Population	6,732	6,877	6,268	3,781	3,822	3,739
Working Women	5,861	5,941	5,070	3,719	3,787	3,216
Average (Potential) Wage						
Working Women	2.019	2.008	2.104	1.528	1.540	1.539
Nonworking Women	2.072	2.083	2.240	1.451	1.329	1.106
Participation Rate						
P	.316	.361	.164	.437	.487	.336
Z	−0.48	−0.36	−0.98	−0.16	−0.03	−0.42

[a] The total includes also mothers with two children younger than three years of age who are not reported in the table.
[b] Wife's earnings excluded.
[c] Given in percent.
[d] Young children are three years of age or less.

and the analysis is therefore limited to the short-run determinants of the housewives' value of time. Likewise, the income measured is current income and does not capture the effect of permanent income on the participation behavior. Finally, the average wage variable is far from being ideal. The 1960 Census reports the number of working hours in the week preceding the census week, the number of weeks worked in 1959, and the wife's earnings in 1959. To obtain a measure of the hourly wage I divided the 1959 earnings by the product of the 1960 weekly hours and the 1959 annual weeks worked and averaged this measure over all women working both in 1959 and in 1960 who belonged to the specific cell. Some of the characteristics of the women belonging to the sample are described in Table 1.

Equation (45) was estimated separately for whites and nonwhites, and within each race group for all women, women without a child younger than three years old and women with one child younger than three.[20] To correct for differences in cell size I fitted a weighted regression, the weights being the number of working women in the cell (i.e., the number of observations used to compute $\overline{W}$). The results of this regression are reported in Table 2.

Of the twelve regressions reported in Table 2, all are significant (at a level of significance of 0.01) except for those relating to white mothers with a child younger

[20] Originally, I distinguished between women with no child less than three years old, mothers of one child less than three, and mothers of two or more children less than three. The last group was, however, too small to allow the estimation of equation (45).

[a] Income is measured in units of $10,000.
[b] Young children are three years of age or less.

than three years old. The coefficients of Z and Z^* are positive and significant for all the remaining ten regressions, but the income coefficient, though positive as expected, is significant only in the case of white women. The standard deviation of the wage offer distribution is found to be in the range of 50–65 cents per hour. The standard deviation of the price of time distribution is 35–43 cents per hour for nonwhites and somewhat lower (22–28 cents per hour) for white women. An increase in the husband's annual earnings of one thousand dollars (roughly 50 cents an hour) increases the mean value of time of his wife by about 8.2–8.7 cents per hour when she is white.

These results are essentially upheld when it is assumed that μ_{W^*} is a linear function of the natural logarithm of income (i.e., $\mu_{W^*}=\alpha_0+\alpha_1 \, log \, (I)$) or when the dispersion of W^* is allowed to vary linearly with income. The assumption that μ_{W^*} is a linear function of $log \, (I)$ resulted in significantly inferior estimates in the case of the white women, and did very little to improve the explanatory power of the regression in the case of nonwhites and thus I do not report the results here.

To estimate the mean price of time in the absence of market opportunities (μ_{W^*}) of the women belonging to a given age-education-income group I computed for each cell

$$\mu_{W^*} = \overline{W} - b_2 Z \tag{46}$$

where it is assumed that $\sigma_W=0$, and

$$\mu_{W^*} = \overline{W} - b_2 Z^* \tag{47}$$

where it is assumed that $\sigma_{W^*}=0$. Weighting each cell by the number of women belonging to the group and summing the estimates over all cells yields an estimate of the mean price of time in the population. Table 3 presents estimates of μ_{W^*} based on the estimates of σ_{W^*} and σ_W (i.e., the coefficient b_2) shown in table 2.

It is found that the mean price of time

[a] Young children are three years of age or less.
[b] Given in percent.

of white married women exceeds that of nonwhites by 40–50 percent (the difference is even larger when one compares white women with no child younger than three years of age with the corresponding nonwhite group). Only part of the difference between these two means can be explained by income differences. The average income of a white family (wife's earnings excluded) exceeds that of a nonwhite family by almost 80 percent ($6,732 vs. $3,781). (See Table 1.) Income seems to have a more substantial effect on the price of time of white women than on the price of time of nonwhites (the exception being nonwhite women with young children). Computing the elasticity of the price of time with respect to income ($\epsilon_{W^*I} = b_1(\bar{I}/\mu_{W^*})$), the estimate in the case of white women is 0.27–0.34 while that of nonwhites is only 0.12–0.14 (see Table 3).[21]

Even if one adopts the highest of these estimates, income can explain at most one-half of the difference between the white and nonwhite mean price of time. To explain the other half, one has to rely on variables whose effect on W^* has not been investigated in this study, such as family composition, and the age and education of the husband and the wife. For example, Table 1 indicates that the nonwhites are more heavily concentrated in the lower age and education groups. If age and education increase the productivity of the woman in the nonmarket as well as in the market sector, this difference should result in a lower mean value of time of nonwhites as compared with white women.

[21] This difference in elasticities can be interpreted as an increase in the sensitivity of the price of time to changes in income as income increases. It is difficult, however, to explain in this way the high value of ϵ_{W^*I} observed in the case of nonwhite mothers of young children.

The attempt to examine the effect of young children on their mothers' value of time was only partly successful. I could not derive meaningful estimates of the parameters of $f(W, W^*)$ for the case of white women with one child younger than three years of age, and the analysis must, therefore, be confined to the nonwhite group.[22]

The difference between the price of time of nonwhite women with one young child and the price of time of women with none is relatively small (6–8 percent). Given the small difference in family income of the two groups (about 2 percent), this difference would have been only slightly affected had we corrected our estimates for income differentials. There is no way of evaluating how this difference would have reacted to an adjustment for age and education. Mothers of young children are, naturally, concentrated in the younger and more educated cohorts. The differences in age composition and education composition tend to offset each other in their effect on the woman's market productivity (the potential wage of the two groups is almost identical). Thus, there is good reason to believe that an adjustment for age and education would not have changed the observed order of magnitude of the child effect.

Assuming $\sigma_{W^*}=0$ the estimate of the average price of time of housewives belonging to a given age-education-income group ($\overline{W}^*$) equals the mean price of time of married women in that group (μ_{W^*}). To obtain an estimate of the average for the whole population one has to compute a weighted average of these estimates, the weights being the number of housewives in each cell. The average $\overline{W}^*$ must not necessarily equal the average value of μ_{W^*} because of different weighting schemes. The estimate of $\overline{W}^*$ usually differs from that of μ_{W^*} insofar as the portion housewives constitute of married women varies from cell to cell.

When it is assumed that $\sigma_W=0$, one has to compute (42) and (43) to obtain an estimate of the housewive's average price of time for each cell. Weighting these estimates by the number of housewives in each cell one obtains an estimate of $\overline{W}^*$ for the whole population. Our estimate of $\overline{W}^*$ are described in Table 3.

Assuming that all women belonging to the same cell expect the same wage rate (i.e., $\sigma_W=0$), it is found that the housewives' average price of time exceeds their average potential wage rate by 14 percent when they are white, and by 22 percent when they are nonwhite. The white nonwhite differentials are explained by the somewhat higher estimate of σ_{W^*} for the nonwhite women, and reflect the different rates of participation resulting in different value of $\bar{y}$. The margins between the price of time $\overline{W}^*$ and the potential wage rate $\overline{W}_H$ are only a little higher if one compares nonwhite housewives with young children with housewives with none.

If one adopts the second assumption (i.e., $\sigma_{W^*}=0$) the housewives' average price of time is expected to fall short of their average potential wage rate. The value of time of white housewives is found to be 80 percent of their potential wage rate while that of nonwhites is 74 percent. The margins for nonwhites with and without children are very similar (70 and 76 percent, respectively).

The preceding comparisons focused on the relationship between the price housewives assign to their own time and what is believed to be their wage expectations. A more ready available basis for comparison is the average wage of working women.

[22] One cannot derive any conclusions from the comparison of the estimate of μ_{W^*} for all whites and that for whites with no young children less than three years of age since the former is not a weighted average of the estimates of μ_{W^*} of whites with young children and μ_{W^*} of whites without young children.

This average wage differs from what is assumed to be the housewives' average potential wage because of the different age and education composition of working and nonworking women.

There is only a very small difference between the average wage of working women ($\overline{W}_W$) and that of housewives ($\overline{W}_H$) both in the case of white and nonwhite women. However, since the former exceeds the latter in the case of nonwhites (by about 2 percent) but the relationship is reversed in the case of whites (the margin being less than 3 percent), the differential between the ratio of $\overline{W}^*/\overline{W}_W$ of whites to nonwhites observed under the assumption $\sigma_W=0$ disappears when one uses as the basis of comparison the average wage of working women ($\overline{W}^*/\overline{W}_W$ being 18–19 percent). On the other hand, these differentials widen if one assumes $\sigma_{W^*}=0$ ($\overline{W}^*/\overline{W}_W$ for whites increasing to 82 percent and $\overline{W}^*/\overline{W}_W$ for nonwhites dropping to 72 percent).

The effect of a change in the basis of comparison is somewhat more pronounced if one compares nonwhites with and without young children. The average wage of a nonwhite working woman with no young child is almost identical with that of a working woman with one young child. The average wage of a working woman exceeds the housewife's potential wage by 11–13 percent. The difference between $\overline{W}^*$ and $\overline{W}_H$ reported in the case of nonwhites (when it as assumed $\sigma_W=0$) is, therefore, cut by one-half when one compares $\overline{W}^*$ with $\overline{W}_W$. On the other hand, the margins increase if one assumes $\sigma_{W^*}=0$, the ratio of $\overline{W}^*/\overline{W}_W$ falling to a level of 0.6–0.7.

V. Some Concluding Remarks

A common practice is to equate the value of time of housewives with that of working women. Given our estimates under two extreme assumptions this practice may involve an error of the magnitude of close to 20 percent in the case of white housewives and an even larger margin of error in the case of nonwhites. One should realize that this margin varies with the housewife's characteristics (for example, her age, education, income, number and age composition of children). Its magnitude depends on the divergence of the wage rate of working women from the potential wage of the nonworking and the relationship between the housewives' average price of time and their expected wage. Thus, it seems that the possible error incurred in the case of nonwhite women is much larger, and may involve an overestimate of $\overline{W}^*$ of up to almost 50 percent.

In another paper (1973), I applied very similar methods to estimate the value of housewives' time in Israel. The labor force participation rate of Israeli married women in 1969 (36 percent) is somewhat higher than the one reported for whites in our sample (32 percent). Assuming $\sigma_W=0$ the estimated coefficient of variation of the price of time distribution (σ_{W^*}/μ_{W^*}) is almost identical for the Israeli and white American women (14 and 13 percent, respectively). Consequently, the ratio of the mean price of time ($\hat{\mu}_W$) and the average potential wage ($\overline{W}_T$) is almost the same in the two groups (1.08 and 1.07, respectively). The income elasticity of W^* is somewhat higher for Israeli women (0.36 vs. 0.27).

The similarity in results is less pronounced if one opts for the assumption $\sigma_{W^*}=0$. The ratio of σ_W to μ_{W^*} is greater for American women than for the Israeli (0.24 vs. 0.14) resulting in a lower $\mu_{W^*}/\overline{W}_T$ ratio for the first group (0.8 vs. 0.9). The estimate of ϵ_{W^*I} is still higher in the Israeli case (0.46 vs. 0.34).

The similarity of some of these results may be comforting but one has to bear in mind the limitations of our model. The assumption that the price of time is unaffected by changes in age and education is

clearly too restrictive. Attempts to remove this assumption according to the lines suggested in my earlier paper have proven to be unsuccessful. As shown by the comparisons of whites and nonwhites, and women with and without young children, the relaxing of this assumption is crucial for the understanding of the determinants of the price of time. The use of disaggregated data may offer a solution to this problem but may involve some other difficulties.

Finally, our procedure is based on the implicit assumption that work in the market and home production do not involve any direct utilities. Even casual observations would indicate that this assumption is wrong. Recognizing the shortcomings of these estimates one has to end this paper with an adequate warning: "Fragile! Handle (the estimates) with care!"

Transactions Costs, the Wage Rate, and the Demand for Money

By Dean S. Dutton and William P. Gramm*

Recent work on the demand for money has focused on the productivity of money in yielding services (see Thomas Saving, Jürg Niehans, and Karl Brunner and Allan Meltzer). In the models of Saving and Niehans the use of money reduces transactions time. From such models the traditional results can be derived which emphasize the volume of transactions and the interest rate as determinants of the demand for money. However, if the use of money saves transactions time, it increases the amount of leisure. This suggests an additional determinant of the demand for money, the consumer's valuation of time, i.e., the wage rate. Not only does the demand for money depend on the transacting to be undertaken and the cost of holding money but also on the valuation of the resources which the use of money saves. In equilibrium the marginal valuation of an hour of leisure must be equal to the wage rate. From the assumption of money's usefulness in reducing transactions time it follows that a unit of leisure may be purchased either by reducing work or by increasing money balances. Thus in equilibrium the consumer holds just that level of money balances at which the marginal cost of purchasing an extra unit of leisure via an increase in money holdings would be equal to the wage rate. A change in the wage rate, given the opportunity cost of holding money, results therefore in a change in the relative price of the two ways of purchasing leisure and thereby produces both an income and substitution effect on the demand for money. There is thus a relation between the wage rate and the demand for money independently of changes in income. From our analysis it follows that the demand for money is not determined by but is simultaneously determined with the volume of transactions to be undertaken and the level of income.

The recognition of the leisure time valuation effect of a wage rate change yields both empirical and theoretical implications. For example, the realization of the presence of a leisure time valuation effect in the demand for money offers additional insight into the empirical criteria required to confirm economies of scale in transactions balances. Further the leisure time valuation effect of a change in the wage rate produces a previously neglected effect which alters the macroeconomic adjustment process. Such an effect functions both in the traditional adjustment mechanism where wages and prices are flexible and in the so-called disequilibrium context where traditional adjustment processes do not function. In the disequilibrium model the leisure-price substitution effect provides a theoretical basis for previous assertions about disequilibrium economic behavior and produces adjustment toward equilibrium even in the absence of the traditional adjustment mechanism.

I. The Model

To preserve the dynamic aspects of intertemporal utility maximization and

* Brigham Young University and Texas A&M University, respectively. We are indebted to Thomas Saving for suggestions and criticisms during the various stages of the evolution of this paper. George Borts and an anonymous referee have also made significant contributions to the paper. We also acknowledge the support of a Brigham Young University Research Grant and a Texas A&M Foundation Grant.

yet maintain simplicity, let us assume the consumer behaves so as to maximize

$$(1) \qquad U = U(c, l, a_1)$$

where U is total utility attainment, c is consumption during the period, l is the amount of leisure time taken in the period, and a_1 is the real value of assets held at the end of the period. The assets held at the end of the period form a proxy for future consumption and leisure.

The consumer faces an income constraint (2) and a time constraint (3),

$$(2) \qquad y = wL$$

$$(3) \qquad L + l + T = 1$$

where y is income, w is the wage rate, L is the amount of time spent working, and T is the amount of time spent transacting. Equation (3) states that the three usages of time are mutually exclusive and that their sum exhausts the interval which is arbitrarily defined as 1.

We assume that there are four assets which the consumer can hold; $\bar{m}$, the average stock of money; $\bar{y}$, the average stock of earned income or produced goods; $\bar{c}$, the average stock of consumption goods; and b, bonds which yield rate of interest r. Those assets not held in the form of $\bar{m}$, $\bar{y}$, or $\bar{c}$ are then invested in bonds and earn interest. For simplicity let us assume that income and consumption occur continuously over the time interval and that interest is earned for the portion of the interval during which bonds are held. All arguments of the utility function and the constraints are stated in real terms so that the real value of assets at the end of the period is

$$(4) \quad a_1 = (y-c) + \int_0^1 r(1-t)(y-c)dt + (1+r)a_0 - \sum_i \left(r + \delta_i + \int_0^1 r(1-t)\delta_i dt\right)i$$

where the subscript i identifies $\bar{m}$, $\bar{y}$, or $\bar{c}$ and the variable i measures their quantity; a_0 is equal to initial assets; and δ_i is the real holding cost on the ith stock. The value of assets held at the end of the period is equal to total income earned during the period minus total consumption during the period, plus the interest earnings or payments during the period on the difference $(y-c)$, plus the capitalized value of initial assets, minus the sum of interest lost on the average level of stocks held, minus the storage costs of holding the stocks including the interest lost on the δ_i payments which are assumed to be paid continuously. The time spent in transacting may be formulated as[1]

$$(5) \quad T = T(y, c, \bar{m}, \bar{y}, \bar{c}); \quad T_y > 0,\ T_c > 0,\ T_{\bar{m}},\ T_{\bar{y}},\ T_{\bar{c}} < 0$$

Given w, r, a_0, δ_i the consumer chooses c, l, a_1, y, $\bar{m}$, $\bar{y}$, $\bar{c}$ so as to maximize utility. The function to be maximized is

$$(6) \quad V = U(c, l, a_1) - \lambda_1\left\{a_1 - \left[\left(1+\frac{r}{2}\right)(y-c) + (1+r)a_0 + \sum_i\left(r + \left(1+\frac{r}{2}\right)\delta_i\right)i\right]\right\} - \lambda_2\{y - w[1 - l - T(y, c, \bar{m}, \bar{y}, \bar{c})]\} \quad (i = \bar{m}, \bar{y}, \bar{c})$$

The first-order conditions for the maximization of (6) are

$$(7)\ (a) \quad U_c = \lambda_1\left(1+\frac{r}{2}\right) + \lambda_2 w T_c = \lambda_1\left(1+\frac{r}{2}\right)\frac{[1 + w(T_y + T_c)]}{1 + wT_y}$$

[1] See Saving's analysis of the transactions time function for the general properties of equation (5). As in Saving's analysis, bonds do not enter the transactions time function, and they are assumed to have no holding costs. These assumptions are made for simplicity purposes since we wish to focus attention on money.

$$\text{(b)}\quad U_l = \lambda_2 w = \frac{\lambda_1\left(1+\frac{r}{2}\right)w}{1+wT_y}$$

$$\text{(c)}\quad U_{a_1} = \lambda_1$$

$$\text{(d)}\quad \lambda_1\left(1+\frac{r}{2}\right) = \lambda_2(1+wT_y)$$

$$\text{(e)}\quad -\frac{\lambda_2 wT_{\bar{m}}}{\lambda_1} = -\frac{\left(1+\frac{r}{2}\right)wT_{\bar{m}}}{1+wT_y} = \left[r+\left(1+\frac{r}{2}\right)\delta_{\bar{m}}\right]$$

$$\text{(f)}\quad -\frac{\lambda_2 wT_{\bar{y}}}{\lambda_1} = -\frac{\left(1+\frac{r}{2}\right)wT_{\bar{y}}}{1+wT_y} = \left[r+\left(1+\frac{r}{2}\right)\delta_{\bar{y}}\right]$$

$$\text{(g)}\quad -\frac{\lambda_2 wT_{\bar{c}}}{\lambda_1} = -\frac{\left(1+\frac{r}{2}\right)wT_{\bar{c}}}{1+wT_y} = \left[r+\left(1+\frac{r}{2}\right)\delta_{\bar{c}}\right]$$

The terms on the right-hand side of (7a) and (7b) are equal to λ_1 times the relative opportunity costs of consumption and leisure, respectively. Equation (7a) specifies that the marginal utility of consumption must equal its opportunity cost in terms of the marginal utility of asset acquisition foregone and the transactions time cost incurred valued at the wage rate. Equation (7b) requires that the marginal utility of leisure equal the wage rate valued in terms of the marginal utility of end of the period assets. Equation (7c) defines λ_1 as the marginal utility of end of the period assets, and (7d) yields the relation between λ_1 and λ_2. Equations (7e), (7f), and (7g) require that the marginal returns to holding average stocks of money balances, goods produced and goods consumed equal the respective opportunity cost of holding the noninterest bearing stocks in terms of the interest earnings foregone and holding costs incurred. The term $(1+wT_y)$ in denominators of a, b, e, f, and g reflects the fact that the transactions time saved cannot be entirely converted into income, given fixed stocks, because increased income requires increased transactions time.

Equations (7) and (4) plus (3) and (5) substituted into (2) make up nine equations in nine unknowns with six parameters. Solving for the optimum money stock $\bar{m}$, the demand for money can be written as

$$\text{(8)}\qquad \bar{m} = m(w, r, a_0, \delta_{\bar{m}}, \delta_{\bar{y}}, \delta_{\bar{c}})$$

$$\text{(9)}\quad A\begin{bmatrix} dc \\ dl \\ da_1 \\ dy \\ di \\ d\lambda_1 \\ d\lambda_2 \end{bmatrix} = \begin{bmatrix} \frac{\lambda_1}{2} & \lambda_2 T_c & 0 & 0 \\ 0 & \lambda_2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -\frac{\lambda_1}{2} & \lambda_2 T_y & 0 & 0 \\ \lambda_1[1+\delta_j/2] & \lambda_2 T_j & 0 & \lambda_1[1+r/2] \\ -[(y-c)/2+a_0-\sum_i(1+\delta_i/2)i] & 0 & -(1+r) & (1+r/2)j \\ 0 & [1-l-T(y,c,i)] & 0 & 0 \end{bmatrix}\begin{bmatrix} dr \\ dw \\ da_0 \\ d\delta_j \end{bmatrix}$$

$$
\text{(9a)}\quad
\begin{bmatrix}

$$

$$
\text{(d)}\quad \frac{\partial \bar{m}}{\partial \delta_j} = \frac{\lambda_1(1 + r/2) D_{j\bar{m}}}{D} + \frac{(1 + r/2) j D_{\lambda_1 \bar{m}}}{D} \qquad (j = \bar{m}, \bar{y}, \bar{c})
$$

The derivatives of (8) can be derived by totally differentiating the system of equations (7), (4), and (2) after substituting in (3) and (5). The differentiation yields the system shown as (9), where A is the 9x9 matrix shown as (9a), and $j,\ i = \bar{m},\ \bar{y},\ \bar{c}$. Solving for the changes in $\bar{m}$ with respect to changes in the parameters, we have the system shown as (10), where D is the determinant of A in (9a) which is assumed to be negative definite as a condition for maximization, and D_{ij} is the cofactor of the ith row and jth column.

In order to specify the nature of the derivatives of the demand for money function both to clarify the source of the various disturbances and to sign the derivates, it is helpful to associate the terms of the equations of (10) with effects about which we can make some assumptions. In this frame of reference, let us gauge the change in the choice variables with respect to a change in $\delta_{\bar{m}}$ the real cost of holding money. Solving for the change in the kth decision variable with respect to $\delta_{\bar{m}}$

$$
\text{(11)}\quad \frac{\partial k}{\partial \delta_{\bar{m}}} = \frac{\lambda_1(1 + r/2) D_{\bar{m}k}}{D} + \frac{(1 + r/2)\bar{m} D_{\lambda_1 k}}{D} \qquad (k = c, l, a_1, y, \bar{m}, \bar{y}, \bar{c})
$$

Note further that

$$\frac{\partial k}{\partial[(1+r)a_0]} = -\frac{D_{\lambda_1 k}}{D} \tag{12}$$

where $(1+r)a_0$ is the end of period capitalized value of the stock of initial real assets. Thus a change in the holding cost of money produces an income and substitution effect on the decision variables. The income term is the capitalized compensation required to maintain the consumer at the same level of utility attainment after $\delta_{\bar{m}}$ changes.

The change in transactions time with respect to a change in the holding cost of money balances may be stated in utility constant form as

$$\left(\frac{\partial T}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} = T_y\left(\frac{\partial y}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + T_c\left(\frac{\partial c}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + T_{\bar{m}}\left(\frac{\partial \bar{m}}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + T_{\bar{y}}\left(\frac{\partial \bar{y}}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + T_{\bar{c}}\left(\frac{\partial \bar{c}}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} \tag{13}$$

Noting from (7d) that $\lambda_1 = \lambda_2(1+wT_y)/(1+r/2)$ and inserting the substitution effect terms from (11) into (13)

$$\left(\frac{\partial T}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} = (1+wT_y)\left(\frac{T_y\lambda_2 D_{\bar{m}y}}{D} + \frac{T_c\lambda_2 D_{\bar{m}c}}{D} + \frac{T_{\bar{m}}\lambda_2 D_{\bar{m}\bar{m}}}{D} + \frac{T_{\bar{c}}\lambda_2 D_{\bar{c}\bar{m}}}{D} + \frac{T_y\lambda_2 D_{\bar{y}\bar{m}}}{D}\right) \tag{14}$$

The last term of (10a) is an income effect term. This may be seen by adding a shift parameter π to the income function in the second constraint of (6) and solving for $\partial\bar{m}/\partial\pi = D_{\lambda_2\bar{m}}/D$. Using the results of (14) and substituting from (13), (11, $k=l$) and noting the presence of the income effect term produced by a parallel shift in the constraint, (10a) can be written as

$$\frac{\partial \bar{m}}{\partial w} = \frac{1}{(1+wT_y)}\left\{\left(\frac{\partial T}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + \left(\frac{\partial l}{\partial \delta_{\bar{m}}}\right)_{\bar{u}}\right\} + [1 - l - T(y, c, \bar{m}, \bar{y}, \bar{c})]\frac{\partial \bar{m}}{\partial \pi} \tag{15}$$

which expresses the derivative of the demand for money with respect to the wage rate in terms of the weighted sum of three other derivatives. The sum $(\partial T/\partial\delta_{\bar{m}})_{\bar{u}} + (\partial l/\partial\delta_{\bar{m}})_{\bar{u}}$ is proportional to the substitution effect of a change in the wage rate and $\partial\bar{m}/\partial\pi$ is proportional to the income effect. Since the weights are positive it remains only to sign the two terms $(\partial T/\partial\delta_{\bar{m}})_{\bar{u}} + (\partial l/\partial\delta_{\bar{m}})_{\bar{u}}$ and $\partial\bar{m}/\partial\pi$ in order to determine the sign of $\partial\bar{m}/\partial w$.

Assuming the normality of goods and inputs $\partial\bar{m}/\partial\pi > 0$. The increased demand for both consumption and leisure as income or assets increase creates an increase in the derived demand for money through the transactions time function. First, in order to satisfy the increased demand for leisure the consumer will reduce work and reduce transactions time by holding larger money balances. Second, in order to consume more—which affects transactions time positively—without enjoying less leisure the consumer will work less and hold larger money balances to offset the effect of increased consumption on transactions time.

Holding utility constant, an increase in $\delta_{\bar{m}}$ which increases the cost of purchasing leisure via money holdings, will induce the consumer to reduce his consumption of leisure and increase desired consumption of goods and holdings of end of period assets. Transactions time will increase first, because money, one input in the transactions time function, has become relatively more expensive (recalling that $\partial T/\partial\bar{m} < 0$), and second because consumption has increased (recalling that

$\partial T/\partial c>0$). Therefore $(\partial T/\partial \delta_{\bar{m}})_{\bar{u}}>0$ and $(\partial l/\partial \delta_{\bar{m}})_{\bar{u}}<0$. Since the increase in the holding cost of money increases the cost of obtaining leisure by reducing transactions time relative to the cost of obtaining leisure via reduction in work time, there will be a substitution by the consumer of work time for transactions time in purchasing his desired level of leisure. That is, because of the change in the relative price the consumer will reduce work time and increase transactions time. Therefore $(\partial L/\partial \delta_{\bar{m}})_{\bar{u}}<0$. Noting that $(\partial T/\partial \delta_{\bar{m}})_{\bar{u}}+(\partial l/\partial \delta_{\bar{m}})_{\bar{u}}+(\partial L/\partial \delta_{\bar{m}})_{\bar{u}}=0$, it then follows that $[(\partial T/\partial \delta_{\bar{m}})_{\bar{u}}+(\partial l/\partial \delta_{\bar{m}})_{\bar{u}}]>0$ and consequently $\partial \bar{m}/\partial w>0$. Given our assumptions, then, it follows that both the substitution effect and the income effect of a change in the wage rate are positive.

The normality of the arguments of the utility function and the transactions time function makes $\partial \bar{m}/\partial a_0>0$. A rise in assets causes a rise in consumption of goods but by normality the consumer is loath to decrease leisure so he holds larger money balances and works less. A rise in assets will thus cause a rise in money holding.

The terms of the derivative of money balances with respect to the interest rate can be identified and partially signed by substituting the relations derived by transformation (11) and formulation (10b) into (10c). After such substitution

$$(16)\quad \frac{\partial \bar{m}}{\partial r} = \left\{\left(\frac{2+\delta_{\bar{m}}}{2+r}\right)\left(\frac{\partial \bar{m}}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + \left(\frac{2+\delta_{\bar{y}}}{2+r}\right)\left(\frac{\partial \bar{y}}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + \left(\frac{2+\delta_{\bar{c}}}{2+r}\right)\left(\frac{\partial \bar{c}}{\partial \delta_{\bar{m}}}\right)_{\bar{u}}\right\} + \frac{1}{2+r}\left(\frac{\partial c}{\partial \delta_{\bar{m}}} - \frac{\partial y}{\partial \delta_{\bar{m}}}\right)_{\bar{u}} + \frac{1}{(1+r)}\left[\frac{(y-c)}{2} + a_0 - \sum_i (1+\delta_i/2)i\right]\frac{\partial \bar{m}}{\partial a_0}$$

The first three terms of (16) are the substitution terms produced on the stocks held by a change in the cost of holding money. Assuming own price dominance of the three effects will not assure the dominance of the first term since each term is weighed by its holding costs. The value of $(\partial \bar{m}/\partial \delta_{\bar{m}})_{\bar{u}}$ is negative, and the values $(\partial \bar{y}/\partial \delta_{\bar{m}})_{\bar{u}}$ and $(\partial \bar{c}/\partial \delta_{\bar{m}})_{\bar{u}}$ are positive or negative depending on whether $\bar{m}$ and $\bar{y}$, $\bar{c}$ are substitutes or complements. The second substitution effect is the effect of a change in $\delta_{\bar{m}}$ on consumption and income. A rise in $\delta_{\bar{m}}$ makes transacting more expensive and reduces both purchases (c) and sales (y) made by the consumer. If the impact of a rise in $\delta_{\bar{m}}$ is symmetric, the substitution effect of a change in $\delta_{\bar{m}}$ is the same on both c and y so that the second substitution term is zero. Assuming the normality of money holding $\partial \bar{m}/\partial a_0>0$, while the sign of $(y-c/2)+a_0-\sum_i (1+\delta_i/2)i$ (the derivative of the a_1 with respect to r), is positive, negative, or zero depending on the relative magnitudes of $(y-c)$, a_0, $\bar{m}$, $\bar{y}$, $\bar{c}$, $\delta_{\bar{m}}$, $\delta_{\bar{y}}$, and $\delta_{\bar{c}}$.

There is thus a negative own price substitution effect, indeterminate cross price substitution effects, indeterminate trade effect, and indeterminate income effect produced on the demand for money when the interest rate changes. The own price substitution effect of a rise in r makes money more expensive to hold and causes $\bar{m}$ to fall. The cross price substitution effects alter the holding of stocks of substitutes and complements. The trade effect alters sales and purchases and its sign depends on whether c or y is more affected by a change in $\delta_{\bar{m}}$. How a rise in r affects wealth and by normality affects the demand for money depends on the composition of a_1 and the sign of $\{[(y-c)/2]+a_0\}$. A rise in the interest rate raises the holding

cost of the noninterest bearing stocks held and lowers wealth. The impact of a rise in the interest rate on $\{[(y-c)/2]+a_0\}$ depends on whether the individual is a net creditor or debtor. If he is a net creditor (debtor) a rise in the interest rate raises (lowers) his wealth. Therefore, for the net debtor the income effect of a change in the interest rate is negative, and for the net creditor it may be positive, negative, or zero depending on the composition of his portfolio.[2]

A change in the holding costs of assets produces both an income and substitution effect on the demand for money as shown in (10d). As assumed in (10b), $-D_{\lambda_1\bar{m}}/D > 0$ so that the income term of (10d) is negative. This can be seen by noting that a rise in the price of a stock increases the price of leisure and lowers wealth. In the own price case where $i=\bar{m}$ the substitution term must be negative as a condition for maximization. When $i=\bar{y}$, $\bar{c}$ the sign of the substitution term of (10d) depends on the assumed relation between $\bar{m}$ and $\bar{y}$ or $\bar{c}$ in the transactions costs function.[3]

II. An Empirical Note

The demand function for money generated by the above analysis (8) states the demand for real money balances as a function of the real wage, the interest rate, the real value of assets and real storage costs on goods produced, goods consumed, and money. Since suitable data are not available for storage costs, the empirical specification of (8) is limited to the real wage (w), the interest rate (r), and the real value of initial assets (a_0). Assuming away distribution effects we may aggregate over individuals' demands for money. Such aggregation eliminates the income effect of a change in the interest rate on internal debt.[4] Since the theoretical analysis above is cast in terms of a general equilibrium system the standard assumption is made regarding the equality of the real money stock and the demand for real balances. The logic of such an assumption is that while society does not determine the nominal stock of money it holds, it does determine the price level and thus the real money stock. Further, the ratio of the money stock held by consumers to the total stock is assumed fixed so that data on the total money stock can be employed in the tests below.

The demand function to be estimated is assumed to be linear in the *logs* of its arguments so that the equation to be estimated is

$$(17)\quad ln\, \bar{m}_t = ln\, \beta_0 + \beta_1\, ln\, w_t + \beta_2\, ln\, r_t + \beta_3\, ln\, a_t + u_t$$

where u_t is assumed $\sim N(0, \sigma^2)$. In estimates of equation (17), three different definitions of the interest rate and four different definitions of the real value of assets were employed. Short-, intermediate- and long-term interest rates were defined

[2] The above analysis follows only if debts are recontracted each time the interest rate changes. Given recontracting holders of bonds as net creditors incur a rise (fall) in wealth as the interest rate rises (falls). If debts were not recontracted the market value of existing bonds would fall (rise) as the interest rate rises (falls).

[3] It is easily shown that the cross price substitution effect depends on the production relation in the transaction time function between $\bar{m}$ and $\bar{y}$, $\bar{c}$. Note for example that

$$\frac{\partial \bar{m}}{\partial \delta_{\bar{y}}} = \frac{\lambda_1(1+r/2)D_{\bar{y}\bar{m}}}{D} + \frac{(1+r/2)\bar{y}D_{\lambda_1\bar{m}}}{D}$$

so that

$$\frac{\lambda_1(1+r/2)D_{\bar{y}\bar{m}}}{D} = \left(\frac{\partial \bar{m}}{\partial \delta_{\bar{y}}}\right)_{\bar{u}}$$

which is positive if $\bar{y}$ and $\bar{m}$ are substitutes and negative if they are complements.

[4] Public debt can be treated as internal debt if individuals take account of the impact of the burden of interest payments on the public debt on future taxes or the flow of government services. In the empirical analysis below, government debt is not counted as part of national wealth so that the expected sign of the income term of (10c) is negative.

as follows:

r_1 (short term) = rate on prime commercial paper (4–6 months),

r_2 (intermediate) = rate on short-term business loans,

r_3 (long term) = Moody's AAA bond yields.

Four definitions of the real value of assets were generated by assuming that the flow of services yielded by government assets are valued by the consumer either at par with the flow of services from private assets or at zero. Demand deposits net of reserves were assumed to be either net additions to total wealth or pure inside money which is the debt of the issuer. Thus

$$(18)\qquad a_1 = \frac{A_T - M_{gS} + C_P + D_d}{P}$$

$$a_2 = \frac{A_T - M_{gS} + M_b}{P}$$

$$a_3 = \frac{A_T - A_g + C_P + D_d}{P}$$

$$a_4 = \frac{A_T - A_g + M_b}{P}$$

where A_T is total nominal nonmonetary wealth, M_{gS} is the nominal value of monetary gold and silver held by the government, C_P is the nominal value of currency held by the public, D_d is the nominal value of demand deposits held by the public, M_b is the nominal monetary base, A_g is the nominal value of government assets, and P is the price level.

Initial estimates of (17) using r_i and a_j yielded Durbin-Watson statistics which indicated the presence of significant positive autocorrelation. Employing a two-step Orcutt procedure (see Donald Cochrane and Guy Orcutt) adjustments were made to eliminate the autocorrelation in the residuals.[5] Table 1 presents the estimates of equation (17) after adjustments have been made for autocorrelation, and the preadjustment Durbin-Watson statistics.

The most consistent result found in Table 1 is the statistical significance of w in all equations estimated. The coefficient of the wage rate is positive and statistically significant at the 1 percent level or better in every equation, regardless of the definition of the interest rate and real assets employed. Since equation (17) is estimated in the *logs* of its arguments, the coefficients of w in Table 1 are the wage rate elasticities of the demand for money. The elasticities vary from 1.27 when r_1 and a_2 are the assumed interest rate and asset level definitions to .76 when r_3, a_1 or r_3, a_3 are employed in the test equation.

The sign of r_i is negative in all equations and statistically significant at the 1 percent level or better in four equations, in all of which r_3, the long-term rate, was employed. The coefficient of the interest rate is statistically significant at the 5 percent level when the intermediate-term rate is employed. When the short-term rate is employed the coefficient of r is statistically significant at the 5 percent level in one equation and at the 10 percent level in the other three equations. The superiority of the long-term rate in producing a significant coefficient for r is compatible with other studies of the demand for money which have used the long-term rate

[5] Assuming a first-order autoregressive disturbance structure

$$u_t = \rho u_{t-1} + \epsilon_t$$

where $\epsilon_t \sim N(0, \sigma^2)$, $\hat{\rho}$ is gauged as follows

$$\hat{\rho} = \frac{\sum_{t=2}^{N} \hat{u}_t \hat{u}_{t-1}}{\sum_{t=1}^{N} \hat{u}_t^2} \left(\frac{N-1}{N}\right)$$

Equation (17) is reformulated as

$$\begin{aligned} \ln \bar{m}_t - \hat{\rho} \ln \bar{m}_{t-1} = \ln \beta_0(1-\hat{\rho}) &+ \beta_1(\ln w_t - \hat{\rho} \ln w_{t-1}) \\ &+ \beta_2(\ln r_{it} - \hat{\rho} \ln r_{it-1}) \\ &+ \beta_3(\ln a_{jt} - \hat{\rho} \ln a_{jt-1}) + \epsilon_t \end{aligned}$$

TABLE 1—ESTIMATES OF EQUATION (17) EMPLOYING THREE DIFFERENT DEFINITIONS OF r AND FOUR DIFFERENT DEFINITIONS OF a USING *U.S.* ANNUAL DATA FOR THE 1919–58 PERIOD

r_2, a_3	0.17	+0.76 (0.26)[a]	−0.49 (0.16)[a]	+0.36 (0.20)[b]	.605	.031
r_1, a_4	0.59	+1.26 (0.28)[a]	−0.07 (0.05)[c]	+0.26 (0.24)	.791	0.55
r_2, a_4	0.27	+0.99 (0.27)[a]	−0.22 (0.11)[b]	+0.34 (0.21)[c]	.617	0.33
r_3, a_4	0.23	+0.87 (0.26)[a]	−0.52 (0.16)[a]	+0.27 (0.20)[c]	.621	0.31

[a] Statistically significant at the 1 percent level.
[b] Statistically significant at the 5 percent level.
[c] Statistically significant at the 10 percent level.

Note: The d reported is for the original equation before corrections were made for the presence of autocorrelation. Standard errors are in parenthesis below coefficients.

Sources: Data for M, P, r_1, r_2, r_3, and w from 1919–57 were taken from U.S. Bureau of the Census, pp. 646, 125–126, 654, 655, 656, and 692, respectively. The various asset variables were calculated using data from R. W. Goldsmith (1955, 1962).

(Meltzer, p. 140), (Gregory Chow, p. 128). Further the highest interest elasticities are obtained when the maturity length of the interest rate is increased. However, the interest elasticities of r_3 are smaller than those obtained by Meltzer using traditional formulations of the demand for money function (pp. 134, 139, 143).

The various definitions of the real value of asset holdings have the expected positive sign in all equations and the coefficient of a is statistically significant at

the 5 percent level in six equations and at the 10 percent level in four equations. Since the wage rate has an income term as formulated in equation (11a), the elasticity of the asset variable would be expected to be lower than in an equation where only r and a are employed in the test equation. Meltzer, employing only r and a for the 1900–58 period, found the asset elasticity of the demand for real money balances to be 1.11 (p. 134) as compared with the .46 to .26 coefficients shown in Table 1.[6]

III. Theoretical and Empirical Implications in Disequilibrium States

The leisure time valuation or substitution effect of a change in the wage rate on the demand for money has important implications with regard to the adjustment process both in the traditional cases where wages and prices are flexible, and instantaneous adjustment is assumed, and in so-called disequilibrium systems where wages and prices are partially invariant and markets do not adjust. It is in the latter cases that the impact of the leisure time valuation or substitution effect on the demand for money appears most novel.

The leisure time valuation effect on the demand for money is very interesting when viewed within the context of the disequilibrium analysis of Robert Barro and Herschel Grossman. From their model, it follows that a reduction in commodity demand and output produces a decline in the demand for labor with a corresponding reduction in employment. Even if wages do fall in response to the resulting excess supply of labor, they conclude that the only result is to induce man-hours of labor to leave the labor force, not to increase the quantity of man-hours of labor demanded. Our analysis, when applied to this model, supplies a force which acts to restore equilibrium in both the commodity and labor markets. Take the Barro-Grossman example of excess labor supply resulting from excess supply in the commodities market (pp. 88–90). Consumers find themselves oversupplied with leisure due to involuntary unemployment and as a result of money's role in providing leisure there is a reduction in the demand for money. To the involuntarily unemployed the wage rate is no longer the marginal cost of leisure. To the extent that wages fall in response to the excess supply of labor there is a further reduction in the demand for money by those who are still employed. This excess supply of money tends to increase commodity demand and thus labor demand, employment, and output.

In the Barro-Grossman case of excess commodity demand (pp. 90–92) our analysis gives their results a choice theoretic foundation and extends them somewhat. They postulate that consumers may react to frustrated commodity demand in two ways: first, by involuntarily augmenting money balances or second, by reducing labor supply. They conclude that generally some combination of the two options will always be optimal. According to our analysis, frustrated commodity demand would be assumed to mean frustrated consumer searches and therefore a shift in the transactions time function. In terms of the first-order conditions (7) this would mean an increase in the price of consumption through an increased T_c. Since the price of consumption relative to leisure has risen, consumers will want to consume less commodities and more leisure directly by reducing work. The fall in work time, given

[6] Meltzer employs a definition of wealth which differs from the four employed in the test above. He excludes all government assets but includes all government debt. This is equivalent to assuming that the consumer valuation of the flow of services from government assets is zero and that consumers do not respond to changes in the real tax burden produced by changes in the level of interest-bearing government debt.

the wage rate, will reduce income, y, and, therefore, reduce T_y in the denominator of (7e), (7f), (7g). The equilibrium condition (7e) is again satisfied by increasing money balances which reduces $T_{\bar{m}}$. This yields a theoretical basis for the Barro-Grosman results of reduced labor supply and increased demand for money.[7]

In the presence of involuntary unemployment the wage rate overstates the opportunity cost of time and the presence of involuntary unemployment would be expected to distort the relation between the wage rate and the demand for money. It is, therefore, useful to reformulate the empirical specification of the demand for money, entering the unemployment rate (γ) into the demand for money function as an explanatory variable. Since for the unemployed the valuation of time (V_T) is less than the market wage rate, it follows that $[(\partial\bar{m}/\partial V_T)(\partial V_T/\partial\gamma)]<0$. Adding the unemployment rate as an explanatory variable of (17) and employing the definitions of r and a used in Section II, the results of the respecification of the demand for money equation are shown in Table 2.

The estimates of Table 2 are those obtained after the Cochrane-Orcutt Interative Technique for eliminating autocorrelation was employed. Since estimates of ρ were approximately 1, the constant term had to be suppressed. While the absence of a constant term tends to bias the estimate of R^2 downward, in every equation employing γ the R^2 is .99. The overall fit is, therefore, improved by introducing the disequilibrium phenomenon into the test equation. Further the coefficient of the unemployment rate is negative and statistically significient at the 1 percent level in every equation. The coefficient of the wage rate is positive and statistically significant at the 1 percent level when the short-term interest rate is employed and at the 5 percent level when the intermediate-term rate is employed. The coefficient of the level of assets is not statistically significant at the 10 percent level in any equation and in many cases it has the wrong sign.[8]

The results of Table 2 suggest that the disequilibrium effect of unemployment had the expected negative effect on the demand for money. To gauge the potential magnitude of the leisure time valuation effect of unemployment, we may employ the .07 estimate of the elasticity of demand for money with respect to the unemployment rate to estimate the decline in money holding in response to unemployment's effect

[7] The analysis can be extended further. The increase in the demand for money caused by the frustrated commodity demand tends to eliminate the excess demand in the commodity market. On the other hand, however, the decreased supply of labor tends to reduce aggregate supply and thus tends to offset the reduction in excess commodity demand caused by increased demand for money. There is still another effect, however. The reduction in the supply of labor puts upward pressure on wages, and increased wages increase the demand for money which again tends to reduce the excess demand in the commodity market. There are thus forces which tend to both reduce and accentuate the initial excess commodity demand. Our observations of a stable system would lead us to believe, however, that the forces predominate which work to eliminate excess commodity demand.

[8] It is interesting to compare the results obtained by employing income instead of the wage rate in the estimate of the demand for money function. From Table 2, with definitions r_1, a_1:

$$\begin{array}{llllll} \bar{m}= & 0.29\,w & -0.11\,r & +0.08\,a & -0.07\,\gamma & (R^2=.99) \\ & (0.09)\dagger & (0.04)\dagger & (0.24) & (0.02)\dagger & \end{array}$$

Employing y in place of w

$$\begin{array}{llllll} \bar{m}= & 0.41\,y & -0.14\,r & -0.39\,a & -0.03\,\gamma & (R^2=.99) \\ & (0.18)^* & (0.04)\dagger & (0.12) & (0.03) & \end{array}$$

The dagger indicates significance at the 1 percent level, and the asterisk at 5 percent. Though the coefficient of y is positive and statistically significant at the 5 percent level, the elasticity of the demand for money with respect to y is larger than the elasticity of the demand for money with respect to w. Further, the coefficient of γ in the equation employing y is not statistically significant at the 10 percent level. This result could reflect the fact that measured y is encompassing some of the impact of employment conditions so that demand for money functions fitted employing y yield good fits because y yields the impact of w after leisure choice decisions have been made and also picks up the impact of employment conditions. This supposition is borne out by the fact that replacing w with y in the general equilibrium formulation of (17) raises the R^2 of the equation from .80 to .99.

on marginal time valuation. In the recession of the 1950's, for example, the magnitudes are $6.04 billion in 1958 and $9.06 billion in 1954. The results of Table 2, therefore, suggest that the empirical magnitude of the leisure time valuation effect produced by involuntary unemployment on spending is not insignificant and indeed that such an effect complements the real-balance effect in producing a self-adjusting economic system.

IV. Conclusions and Implications

Given the assumption of normality, an increase in the wage rate always leads to an increase in income and consumption,

which in turn tends to increase transactions time. Since both leisure and consumption enter the utility function, the consumer is loath to increase transactions time at the expense of leisure. In order to maintain or even increase his leisure time the consumer is induced to hold larger money balances. This increase in money balances demanded, associated with an increase in income, is the result of a resource or income effect caused by an increase in the wage rate. This reasoning, whereby an increase in the demand for money balances is associated with an increase in transactions, yields the traditional transactions motive for holding money. In addition, there is another effect, not considered in traditional analysis, which indicates why an increase in income caused by an increase in the wage rate will lead to an increase in the demand for money. This is the leisure time valuation effect. Since a unit of leisure may be purchased by decreasing work or by increasing money balances, an increase in the wage rate results therefore in an increase in the relative price of purchasing leisure by decreasing work. Thus it follows that an increase in the wage rate will lead to an increased demand for money independent of any increase in transactions.

Considering the net result of both the resource and leisure time valuation effects, if a rise in income, wage rate constant, produced a proportionate rise in the demand for money, then the total increase in the demand for money, produced by an increase in the wage rate associated with a rise in income, should be greater than proportionate to the increase in income due to the leisure valuation effect. Thus an income elasticity (which includes both the resource and leisure valuation effects) less than unity is not necessary for the confirmation of William Baumol's and James Tobin's models which predict economies of scale in the holding of transactions balances.[9] If the leisure valuation effect is a significant determinant of the demand for money, an income elasticity of one would indicate economies of scale in transactions balances. If on the other hand, the resource effect elasticity is equal to one, then an income elasticity greater than one would be implied when both the resource and leisure valuation effects are taken into account.

When viewed in the context of disequilibrium, the leisure time valuation effect provides a theoretical explanation of the spillover effects among the money, labor, and commodity markets produced by the impact of the individual's employment condition on his valuation of time. Specifically, unemployment or overemployment affect the individual's valuation of time and affect the individual's demand for money and commodities by altering the valuation of the service money provides.

The tentative empirical results of Table 2 suggest that the relation between the unemployment rate and the demand for money is negative and statistically significant. Further, if the elasticity of the demand for money presented in Table 2 is used to estimate the magnitude of the leisure time valuation effect, the magnitudes gauged even for mild recessions appears significant. Such results suggest that the leisure time valuation effect might form a complement to the real-balance effect in producing automatic adjustment to full employment.

Given an invariant demand for money function and an exogenous money stock, a fall in prices increases real-money balances and stimulates spending. By the leisure time valuation effect, a fall in the wage

[9] Employing the standard formulation of the demand for money, which incorporates only the resource effect, Meltzer, p. 220, has concluded that an income or wealth elasticity less than unity would confirm economies of scale in holding transactions balances.

rate or a rise in unemployment will decrease the demand for money. The Invisible Hand is thus more powerful than previously supposed since changes in the wage rate and unemployment yield a new dimension to the adjustment process.

Limit Pricing, Potential Entry, and Barriers to Entry

By David P. Baron*

A major advance in the theory of imperfect competition has been the recognition that established firms must take into account possible actions by potential as well as by existing competitors. The empirical research on potential entry has tended to focus on the effects of concentration and barriers to entry on industry profits and price levels, while theoretical study has emphasized the limit pricing behavior of established firms. The study of barriers to entry was pioneered by Joe Bain (1956), who investigated barriers created by 1) product differentiation, 2) absolute cost advantages, and 3) economies of large scale operations. Paolo Sylos-Labini emphasized the effects of returns to scale as a barrier to entry, and Franco Modigliani has provided an important interpretation of the early work of Bain and Sylos-Labini. Empirical studies by Bain and H. Michael Mann (1966) indicate a positive relationship between concentration and profitability, while Marshall Hall and Leonard Weiss found that "Concentration would seem to be less important than the capital requirements barrier as a determinant of profitability" (p. 327).

The theoretical study of the impact of potential entry was begun by Bain (1949) who first introduced the notion that potential competition may lead established firms to sacrifice current profit in order to preclude entry. The deterministic theory of potential entry and limit pricing has been advanced by Roy Harrod, Philip Andrews, H R. Edwards, J. R. Hicks, Frank Hahn, B. Peter Pashigian, Graham Pyatt, Darius Gaskins, and by Jagdish Bhagwati, who has provided a survey and analysis of much of this work.

Oliver Williamson first suggested a probabilistic approach to the issue of potential entry in which the established firms assess the probability that a potential entrant will actually enter the industry. Morton Kamien and Nancy Schwartz have developed and interpreted a stationary, probabilistic model in which an established firm chooses a limit price so as to maximize discounted expected profit over an infinite horizon with the time until entry being uncertain. In an earlier paper I analyzed the implications of alternative assumptions regarding the established firm's assessments of the probability of entry and its postentry behavior. The purpose of this paper is to investigate, using a probabilistic model, the effects of potential entry and barriers to entry on the price and profitability of established firms in an industry faced with potential entry.

I. The Model and Optimality Conditions

The model represents an established firm in an industry composed of a number of firms selling differentiated but related products.[1] Given K_n firms in the industry at the end of period $n-1$, an established firm chooses a period n limit price $p_n(K_n)$

* Associate professor of managerial economics and decision sciences, Northwestern University. Support for this study was provided by the National Science Foundation.

[1] The established firm also may be thought of as a single monopolist or as a cartel.

conditional on that number of firms. Based on the limit price and the number of firms in the industry, k_n potential entrants decide to enter the market in period n.[2] The established firm is assumed to be able to alter its price for the next period[3] and hence chooses a price $p_{n+1}(K_{n+1})$ for period $n+1$ where $K_{n+1}=K_n+k_n$. The profit of the established firm in period n is assumed to depend on the number of firms in the industry in that period with profit if no firms enter ($K_{n+1}=K_n$) denoted by $\pi_n(p_n(K_n), K_n)$. If $k_n>0$ firms enter, period n profit is assumed to be reduced. The short-term reaction of the established firm to entry may be characterized in a variety of manners such as those discussed in my earlier paper. Here, the result of that short-term reaction will be reflected in a postentry profit $\pi_n(K_{n+1}) < \pi_n(p_n(K_n), K_n)$ for all $K_{n+1}>K_n$ where $\pi_n(K_{n+1})$ does not depend on the preentry price and is assumed to be constant.[4] The postentry profit may be understood to represent the established firm's initial reaction to entry, while its complete reaction is to choose a price $p_{n+1}(K_{n+1})$ for the next period. The assumption that the profit after entry is less than that prior to entry is in the spirit of the empirical studies of Bain and Mann that indicate a positive relationship between profitability and concentration and agrees with the behavior of classical Cournot markets with entry as considered by Charles Frank, for example. In addition to the profit earned in the industry in question the established firm may earn profit from operations in other industries and that profit is denoted by R_n.

[2] Firms may enter any time before the end of the period, but to simplify the notation and the analysis all entrants will be assumed to enter at the same point in time.

[3] The length of the period may be considered to be defined by the time required for the established firm to respond to entry.

[4] Kamien and Schwartz assume that postentry profit is constant and the same in all periods after entry.

The number of firms that will decide to enter the industry in a period is uncertain, so the established firm is assumed to assess a (subjective) probability distribution on the number of potential entrants that will actually enter the market in each period. The probability of entry is a function of the assessed profitability to the potential entrant from being in the industry.[5] One possible assumption is that the probability of entry depends on the profit earned by the established firms. This assumption will not be employed, however, since it is doubtful that a potential entrant would be able to observe the profit of an established firm, particularly for a multiproduct firm. Also, the profit to an entrant may well be different from that of an established firm because of cost differences and the effect of product differentiation.[6] A potential entrant, however, is able to observe the price charged by an established firm, and that price is an important indicator of the profitability to the potential entrant. No implication is made, however, that a potential entrant believes that the current price will be in effect after entry has taken place. The potential entrant also is likely to believe that the number of firms in the industry affects profitability with a decrease in concentration reducing the likelihood that entry will be profitable.

The probability $G_n(k_n | p_n(K_n), K_n)$ that k_n firms enter in period n thus is a function of the price $p_n(K_n)$ and of the number K_n of firms in the industry. The probability of no more than a specified number m of firms entering the market is assumed to be decreasing in p_n and increasing in K_{n-1} or more formally:

[5] Roger Sherman and Thomas D. Willett utilized an expected utility maximization model for determining if a potential entrant should or should not enter.

[6] The assumption that entry depends on the preentry profit of established firms has been employed by Pyatt and Hahn. The sometimes paradoxical implications of such an assumption were explored in my earlier paper.

$$(1)\quad \sum_{k_n=0}^{m} G_n(k_n \mid p_n, K_n) < \sum_{k_n=0}^{m} G_n(k_n \mid p_n^*, K_n)$$

for $p_n > p_n^*$ and for $m=0, 1, 2, \ldots,$ $n=1, 2, \ldots$, while

$$(2)\quad \sum_{k_n=0}^{m} G_n(k_n \mid p_n, K_n) > \sum_{k_n=0}^{m} G_n(k_n \mid p_n, K_n^*)$$

for $K_n > K_n^*$ and for $m=0, 1, 2, \ldots,$ $n=1, 2, \ldots$

Consequently, as price increases entry is more likely,[7] and as the number of firms in the industry increases entry is less likely. In the terminology of stochastic dominance (see Josef Hadar and William Russell and Giora Hanoch and Haim Levy) the distribution in (1) conditional on p_n^* is dominated in the first degree by the distribution for p_n and similarly in (2) the distribution for K_n is dominated in the first degree by that for K_n^*. In order to avoid paradoxical results, it also is postulated that the industry is such that it is not optimal to encourage firms to enter in the current period in order to reduce the probability of future entry. Similarly, at the price that maximizes the current-period profit the probability of entry is taken to be positive.

The established firms are assumed to maximize the expected utility of profit over an infinite horizon with a utility function that is temporally additive. Let U_n be a monotone increasing, concave, twice continuously differentiable, cardinal utility function for period n and let $\beta \in (0, 1)$ reflect time preference. The optimal expected utility $F_n(K_n)$ for periods $n, n-1, n+2, \ldots$ depends only on the number of firms in the industry at the end of period $n-1$ and is defined as equation (3). The term $F_{n+1}(K_{n+1})$ is the optimal expected utility in periods $n+1, n+2, \cdots$, and is similarly defined. Given that profit is decreasing in the number of firms in the industry and that future entry is preferred to present entry, $F_{n+1}(K_{n+1})$ may be shown to be decreasing in the number of firms in the industry. The profit function is assumed to be concave and continuously differentiable, and for $k_n \geq 1$, G_n is assumed to be continuously differentiable. The optimal price $\hat{p}_n(K_n)$ satisfies the first-order condition[8]

[7] This probabilistic treatment of entry is equivalent to Hicks' case of oligopolistic expectations in which an increase in "close" period output was assumed to increase open period revenue by reducing the "amount" of entry. Hicks' polypolistic expectations may be represented by replacing the inequality in (1) by an equality.

[8] The second-order condition is

$$(1 - \sum G_n)(U_n''(\pi_n')^2 + U_n'\pi_n'') - 2\sum G_n' U_n' \pi_n' - \sum G_n'' M_n(K_n + k_n) < 0$$

where $M_n(K_n+k_n)$ is defined below. A sufficient condition for $\hat{p}_n(K_n)$ to yield a maximum is that $G_n' \geq 0$ and $G_n'' \geq 0$. The second-order condition is assumed to be satisfied at $\hat{p}_n(K_n)$.

$$(3)\quad F_n(K_n) \equiv \max_{P_n(K_n)} \left\{ \left(1 - \sum_{k_n=1}^{\infty} G_n(k_n \mid p_n(K_n), K_n)\right)[U_n(\pi_n(p_n(K_n), K_n) + R_n) + \beta F_{n+1}(K_n)] + \sum_{k_n=1}^{\infty} G_n(k_n \mid p_n(K_n), K_n)[U_n(\pi_n(K_n + k_n) + R_n) + \beta F_{n+1}(K_n + k_n)] \right\}$$

$$(4)\quad \left(1 - \sum_{k_n=1}^{\infty} G_n\right) U_n' \pi_n' - \sum_{k_n=1}^{\infty} G_n' [U_n(\pi_n(\hat{p}_n(K_n), K_n) + R_n) + \beta F_{n+1}(K_n) - U_n(\pi_n(K_n + k_n) + R_n) - \beta F_{n+1}(K_n + k_n)] = 0$$

where $(1 - \sum_{k_n=1}^{\infty} G_n)$ is the probability of no entry. The argument of the functions will be omitted when the meaning is clear. The term in brackets, denoted by $M_n(K_n+k_n)$ is the difference between the optimal expected utility without entry in period n and optimal expected utility with entry. Since $\pi_n(\hat{p}_n(K_n), K_n) > \pi_n(K_n+k_n)$ and $F_{n+1}(K_n) > F_n(K_n+k_n)$ for $k_n \geq 1$, $M_n(K_n+k_n)$ is positive and increasing in k_n. The change in $M_n(K_n+k_n)$ as the distribution of k_n shifts to the right (in the sense of first-degree stochastic dominance) is of the same sign as

$$\sum_{k_n=1}^{\infty} G_n' M_n(K_n + k_n) = \sum_{k_n=0}^{\infty} G_n' [U_n(\pi_n(\hat{p}_n(K_n), K_n) + R_n) + \beta F_{n+1}(K_n) - U_n(\pi_n(K_n + k_n) + R_n) - \beta F_{n+1}(K_n + k_n)]$$

where $\pi_n(K_n+k_n) \equiv \pi_n(\hat{p}_n(K_n), K_n)$ and $F_{n+1}(K_n+k_n) \equiv F_{n+1}(K_n)$ for $k_n = 0$. The shift thus implies that

$$\sum_{k_n=1}^{\infty} G_n M_n(K_n + k_n)$$

is increasing in $p_n(K_n)$ and hence that

$$\sum_{k_n=1}^{\infty} G_n' M_n(K_n + k_n) > 0$$

To satisfy (4) the optimal price is such that the probability of no entry $(1 - \sum_{k_n=1}^{\infty} G_n)$ is positive and since marginal utility is positive, marginal profit is positive. Consequently, the established firm prices below the price that maximizes preentry profit[9] and prices less than the price that makes the probability of entry equal to one.[10] These results hold for any monotone increasing utility function and thus are due to the probabilistic nature of entry and not to the risk preferences reflected by the utility function.

Harrod suggested that if entry is easy the established firm will price equal to average cost in order to prevent entry. If the firm follows this practice in every period, there is no difference between the utility with and without entry, so $M_n(K_n) = 0$. The optimal limit price thus is higher than the price that equals average cost unless, of course, marginal profit is zero at that price. The probabilistic equivalent of Harrod's entry preventing price may be defined as the price $p_n^e(K_n)$ that makes the probability of no entry equal to one or $G_n(k_n=0 \mid p_n^e(K_n), K_n) \equiv 1$. The optimal limit price is at least as great as the entry-preventing price, since otherwise an increase in price would increase profit and leave the probability of entry equal to zero. This result is a prediction of Dale Osborne's finding that entry has occurred in industries using limit pricing. The deterministic entry-preventing price may also be thought of as the lowest price the established firm could set without finding it preferrable to leave the industry. One such price $p_n^*(K_n)$ satisfies

$$(5)\quad (1 - \sum G_n) U_n(\pi_n(p_n^*(K_n), K_n) + R_n) + \sum G_n U_n(\pi_n(K_n + k_n) + R_n) \equiv U_n(R_n)$$

[9] Kamien and Schwartz obtained the same result in a stationary, probabilistic model. They also demonstrate that the preentry profit is constant over time, and a similar result obtains for the model here if U_n, G_n, and R_n are the same in every period.

[10] Hicks' polypolistic expectations implies that $G_n' = 0$ for all k_n, and then the established firm maximizes preentry profit.

The entry-preventing price may be less than $p_n^*(K_n)$, so the established firm may find it impossible to stay in the industry and prevent entry.

II. Risk Aversion and the Optimal Limit Price

The established firm's limit pricing decision involves the risk that profit will be reduced by entry, and the risk preferences reflected in the firm's utility functions U_n affect the level of the limit price. Risk preferences will be measured by the Arrow-Pratt index of absolute risk aversion $r_{U_n}(y) = -U_n''(y)/U_n'(y)$, where U_n'' and U_n' are the second and first derivatives, respectively. The interpretation of the index is that if $r_{U_n}(y)$ increases for all y, as with a shift in risk preferences, the certainty equivalent associated with the risk increases. The certainty equivalent CE_n of period n profit is defined by

$$(6)\quad U_n(CE_n+R_n) \equiv \left(1-\sum_{k_n=1}^{\infty} G_n\right)U_n(\pi_n(\hat{p}_n(K_n), K_n) + R_n) + \sum_{k_n=1}^{\infty} G_n U_n(\pi_n(K_n+k_n)+R_n)$$

and is the minimum amount the firm would accept in exchange for the period n *ex ante* profit.

Given certain properties of the probability distribution, the optimal period n price may be shown to be a decreasing function of risk aversion. That is, let U_n^1 and U_n^2 be two utility functions such that $r_{U_n^1}(y) \geq r_{U_n^2}(y)$ for all y and $r_{U_n^1} > r_{U_n^2}(y)$ for some y with positive probability, and let $\hat{p}_n^1(K_n)>0$ be optimal for U_n^1 and $\hat{p}_n^2(K_n)>0$ be optimal for U_n^2. Rewrite (4) for U_n^2 evaluated at $\hat{p}_n^2(K_n)$ as

$$(7)\quad (1-\sum G_n)\pi_n' - \sum G_n' \phi_n^2(k_n) = 0$$

where $\phi_n^2(k_n) \equiv M_n^2(K_n+k_n)/U_n^{2\prime}(y^2)$ and $y^2 = \pi_n(\hat{p}_n^2(K_n), K_n)+R_n$. John W. Pratt (equation 22, p. 129) has shown that if $r_{U_n^1}(y) > r_{U_n^2}(y)$ for all y, then $(U_n^1(w) - U_n^1(v))/U_n^{1\prime}(y) > (U_n^2(w)-U_n^2(v))/U_n^{2\prime}(y)$ for $y \geq w > v$. To maintain the intertemporal relationship between U_n and U_j, $j\neq n$, scale the utility function U_n^1 so that $U_n^{2\prime}(y^2) = U_n^{1\prime}(y^2)$. An increase in risk aversion thus implies that $\phi_n^1(k_n) > \phi_n^2(k_n)$ for $k_n \geq 1$. A sufficient, but not necessary, condition for risk aversion to decrease the optimal limit price is that $G_n' \geq 0$ for all $k_n \geq 1$,[11] since then (7) for U_n^1 is negative evaluated at $\hat{p}_n^2(K_n)$, so $\hat{p}_n^2(K_n) > \hat{p}_n^1(K_n)$. A necessary condition is that $\Sigma G_n'[\phi_n^1(k_n) - \phi_n^2(k_n)] \,|\, \hat{p}_n^2(k_n) > 0$. To simplify the following discussion, G_n' is assumed to be nonnegative which implies that an increase in prices increases the probability that k_n firms enter, $k_n \geq 1$.

The interpretation of this result is that as the established firm becomes more risk averse it prefers to exchange period n profit for a lower probability of entry and thus reduces price in period n. The risk to the established firm is that potential entrants will actually enter, and the more averse to risk the firm becomes, the more willing it is to sacrifice current profit for future profit. The effect of risk aversion on the limit price makes intuitive sense and may help explain the differences in profit between industries found by Bain, Mann, and Irving Fisher and George Hall. Certainly many other factors such as those considered in the following section on barriers to entry are important as determinants of the limit price, but the analysis here indicates that risk aversion may act to lower the limit price and thus has an effect similar to a barrier to entry in that both tend to make entry less likely. Increased risk aversion also reduces the certainty equivalent.

The effect of profits from other ac-

[11] The condition that $G_n' \geq 0$ for $k_n \geq 1$ implies, but is not implied by, first-degree stochastic dominance.

tivities R_N on the limit price may be determined directly from the risk aversion result. A utility function is said to exhibit decreasing (increasing) (constant) absolute risk aversion if $r_{U_n}(y)$ is a decreasing (increasing) (constant) function of y. An increase in R_n for U_n exhibiting decreasing (increasing) (constant) absolute risk aversion consequently results in an increase (decrease) (no change) in the optimal limit price.[12] Kenneth Arrow has argued that decreasing absolute risk aversion is a reasonable behavioral assumption. For U_n decreasingly absolute risk averse an increase in R_n decreases risk aversion, and the firm is willing to accept a higher probability of entry in exchange for greater profit if no entry occurs.[13]

III. Barriers to Entry and Concentration

The principal barriers to entry considered by Bain are 1) economies of large scale operations, 2) absolute cost advantages, and 3) product differentiation advantages. One general way to consider the effects of barriers to entry on the limit price is to assume that they are reflected by the established firm's assessment of the probability of entry. An increase in the height of barriers to entry will be represented by a shift to the left in the distribution function of k_n for all prices and for all K_n. For a given $p_n(K_n)$ and K_n, higher barriers to entry thus are assumed to increase the probability that fewer than m firms enter for $m=1, 2, \ldots$, and hence result in a distribution dominated in the first degree by the distribution for lower barriers to entry. Such a change in the probability distribution of k_n affects both the established firm's certainty equivalent and its optimal price. Since period n utility and future expected utility $F_{n+1}(K_{n+1})$ are decreasing in k_n, an increase in the height of the barriers to entry increases the expected utility in (3). The established firm would then be less likely to leave the industry and would require a greater payment for the sale of its activities in the industry. Empirical work by Bain and Mann supports the hypothesis that average profits are higher with "very high barriers" than with lower barriers. In the context of the probabilistic model considered here expected utility and the certainty equivalent profit increase as barriers become "higher."

While higher barriers to entry increase the expected utility of the established firm, the optimal price may increase or decrease. In (4) the probability of no entry $(1-\Sigma G_n)$ increases with higher barriers to entry but the G_n' terms also are affected. If the $G_n'/(1-\Sigma G_n)$, $k_n \geq 1$, terms are not increased by the higher barriers to entry, then (4) evaluated at the price optimal with lower barriers to entry is positive and the optimal price is increased. The term $G_n'/(1-\Sigma G_n)$ is referred to as the "hazard rate" in reliability theory, and if an increase in the barriers to entry reduces the hazard (of entry) rate, the optimal price increases.[14] Bain (1956) has argued that the higher are the barriers to entry the closer the limit price is to the profit maximizing price, and for the model considered here a reduction in the hazard rate for all $k_n \geq 1$ is a sufficient, but not a necessary, condition for this result.

Concentration in the industry affects the established firm by influencing profit and the probability of entry. Holding profit constant, an increase in concentra-

[12] This result obtains by letting $U_n^1(y)=U_n(y)$ and $U_n^2(y)=U_n(y+\Delta y)$, $\Delta y>0$, and using the preceding analysis.

[13] If, for example, a potential entrant must pay to an established firm an entry fee in the form of the purchase of the rights to a patented process, R_n is increased and the firm with decreasingly absolute risk averse risk preferences will raise its limit price which increases the probability of further entry, *ceteris paribus*.

[14] Kamien and Schwartz assume that the hazard rate is increasing in the price charged by the established firm.

tion, such as would occur from firms leaving the industry, affects the probability of entry by shifting the distribution function of the number of entrants to the right as indicated in (2). Such a shift decreases expected utility in agreement with the studies of Bain, Mann, and S. A. Rhoades and decreases the limit price if the hazard rate is increased. Changes in concentration also affect profit, however, so the net effect of exit from the industry is difficult to determine without further assumptions.

The effect of economies of large scale operations on entry may also be reflected by changes in the probability of entry. Modigliani concluded that "[the 'highest entry-preventing price'] will tend to be higher the steeper the cost curve, that is the greater the economies of scale" (p. 220). Similarly, Hall and Weiss found that profitability is positively related to the capital requirements barrier to entry. The effect of such a barrier is to shift to the left the distribution function of the number of firms entering. The shift increases the expected utility giving a theoretical prediction of Hall and Weiss' findings. If the shift reduces the hazard rate, the limit price increases as Modigliani suggested.

Absolute cost advantages may have two types of effects on the pricing policies of an established firm. First, the knowledge on the part of potential entrants that an established firm has achieved a cost reduction, through a technological advance, for example, may reduce the assessed probability of entry. Second, a reduction in cost to an established firm may affect the limit price independent of the probability distribution. For example, suppose that an established firm achieves a reduction in fixed costs in period n but that the potential entrants are unaware of it. A reduction in fixed costs in period n has the same effect as an increase in profits R_n from other activities, so a reduction in fixed costs results in an increase (decrease) (no change) in the optimal limit price in period n if the utility function U_n exhibits decreasing (increasing) (constant) absolute risk aversion. A decrease in a constant marginal cost has both a risk aversion effect and a "cost effect." This risk aversion effect occurs because for a fixed output a reduction in marginal cost is equivalent to a decrease in fixed cost. As in the deterministic theory of the firm, the cost effect tends to decrease price by altering the relationship between marginal revenue (utility) and marginal cost. For nondecreasing absolute risk aversion, a decrease in a constant marginal cost results in a decrease in the limit price,[15] but with decreasing absolute risk aversion the limit price may increase if the risk aversion effect exceeds the cost effect.

Bain found that product differentiation, primarily in the form of advertising, played the most important role in building and sustaining barriers to entry in consumer industries. Utilizing assumptions similar to those for price,[16] the optimal product differentiation expenditures may be shown to be greater than the expenditures that maximize current period profit. The firm thus again is willing to exchange current profit for a lower probability of entry. If product differentiation expenditures decrease the hazard rate in (4), the optimal limit price increases.

The impact of industry growth on the behavior of both established firms and potential entrants is an important issue in industrial organization, and in the context of the model presented in this paper growth may affect both profit and the assessed probability of entry. Since shifts in the distribution function of k_n have al-

[15] This result requires that postentry output is less than preentry output.

[16] An increase in product differentiation expenditures is assumed to shift the probability distribution of the number of firms that enter to the left.

ready been considered, only changes in future profit will be considered at this point with the probability distribution for a given price and K_n assumed fixed. If growth increases the difference in future expected utility with and without entry ($[F_{n+1}(K_n)-F_{n+1}(K_n+k_n)]$) and $G'_n \geq 0$ for $k_n \geq 1$, the term $\Sigma G'_n[F_{n+1}(K_n) - F_{n+1}(K_n+k_n)]$ increases and the optimal limit price in period n is decreased to reduce the probability of future entry. If growth lessens the difference, the optimal price will be increased, since entry causes less of a reduction in profitability.

IV. Conclusions

Potential entry has been represented in a probabilistic manner with the probability of entry dependent on the price charged by an established firm and on the number of firms in the industry. With this probabilistic view of entry the optimal limit price is less than the price that maximizes preentry profit and is greater than the price that equates price and average cost. Since the limit pricing decision involves uncertain profits, it seems natural to ask how risk preferences affect the limit price. Given certain properties of the probability distribution, an increase in risk aversion in period n as measured by the Arrow-Pratt index results in a reduction in the period n limit price, since the firm is willing to accept a reduced current period profit in exchange for a lower probability of entry. Barriers to entry may be reflected in the assessed probability of entry with higher barriers being represented by a shift to the left in the distribution function of the number of actual entrants. Higher barriers to entry result in an increased expected utility, and if the hazard rate is reduced, the optimal limit price is increased.

The empirical research on barriers to entry, concentration, and risk adjusted profitability has been characterized by debates regarding what it is that is actually being measured. For example, see the recent papers by Fisher and Hall, Yale Brozen, Mann (1969), and Richard Caves and B. S. Yamey. The results contained herein indicate the individual effects of concentration, barriers to entry, probability assessments, and risk aversion on profitability and price, but attempting to identify and isolate individual effects from empirical data is likely to be extremely difficult.

Wage Determination, Inflation, and the Industrial Structure

By STEPHEN A. ROSS AND MICHAEL L. WACHTER*

The standard analysis of inflation is based on the existence of a short- and long-run Phillips curve or tradeoff between the rate of inflation and unemployment. This tradeoff results from the effects of excess demand pressure on a labor market characterized by money illusion on the part of workers and firms, or by institutional rigidities imposed by labor unions and producer monopolies.[1] Demand-pull and cost-push elements interact in a complex disequilibrium process, and little attempt has been made to derive rigorously the dynamics or the properties of the steady state. Neoclassical economists have attacked this formulation of the Phillips curve largely on the basis of their own analysis of the long-run equilibrium properties of the system.[2] They agree that the Phillips curve may exist in the short run but insist that it does not exist (that is, it is vertical) in the long run.[3] In the long-run expectations are realized so that money illusion is unsustainable, and if the degree and strength of noncompetitive elements are unchanged, they argue that there can be no tradeoff between inflation and unemployment.

It is also argued that monopoly power cannot result in inflation. In particular, unions desire a relative wage advantage over nonunion workers, and monopolies desire a certain profit markup. In equilibrium, both unions and monopolies will have exercised the full power of their noncompetitive advantage. The wage and profit markups are then fixed in real terms, and there will be no incentive to further increase relative wages and prices. As a result the rate of inflation will not be influenced by an *unchanging* level of noncompetitive forces.[4] As stated by Phelps:

> An increase of monopoly power—due, say, to increased concentration—will raise prices relative to wages at any given unemployment rate and productivity level; but once, at the prevailing unemployment rate, the real wage has fallen (relative to productivity) enough

* Associate professors of economics, University of Pennsylvania. The research was supported by a grant from the National Science Foundation.

[1] The present form of the Phillips curve is due largely to the work of George Perry. More recent research, which attempts to refute the neoclassical model and to utilize equations similar to those of Perry, includes the papers by Robert Solow and Robert Gordon.

[2] The neoclassical position is described in the collection of papers in Edmund S. Phelps. See also the article by Milton Friedman.

[3] Attempts to statistically verify the existence of a vertical long-run Phillips curve have largely been unsuccessful, but the new theory continues to gain in popularity. The reasons for this are obvious. First, and most importantly, the standard Phillips curve analysis with its bias towards cost-push explanations of inflation lacks a strong theoretical bias. Secondly, statistical findings are never unequivocal, and since current time-series data do not include any periods of extended inflation, statistical analysis would be biased towards the observation of a long-run negatively sloped Phillips curve. In addition, no specific theory exists to suggest the exact form of the wage equation, so it is not possible to construct an agreed upon test of the neoclassical model.

[4] The neoclassical position is often taken a step further. Although it is agreed that money illusion is a cause of a short-run Phillips curve, the importance of monopoly elements (either on the part of labor or capital) that are of fixed strength is deemphasized even in the short-run tradeoff. Instead, the observation of seemingly noncompetitive behavior is attributed to the cost of information or transactions costs. These costs, like money illusion, are only a short-run phenomenon so that the long-run tradeoff between inflation and unemployment is still vertical.

> to accommodate the higher markup; this process will stop and any continuation of inflation will depend on other sources. [p. 126]

The purpose of this paper is to outline a new view of the relation between inflation and unemployment in a high employment economy. A basic innovation of our approach is that it incorporates noncompetitive behavior and some of the most important institutional features of the modern economy in a systematic manner into the statics and dynamics of the analysis. The presence of noncompetitive elements in a sector of the economy will be shown to provide a new justification for the existence of a short- and long-run tradeoff between inflation and unemployment. The long-run relationship, however, is positive when there is inflation but negative with deflation, which is in sharp contrast to both the neoclassical and the traditional Phillips curve approaches to the subject.

The analysis also gives rise to a number of additional points of interest from both a theoretical and policy viewpoint. First, the stability of the labor market and the aggregate wage-price structure is altered in a complex manner. Although the long-run Phillips curve is c-shaped, to the extent that policy makers understand the workings of the system, the short-run, negatively sloped Phillips curve actually has considerably more stability than it would if based solely on money illusion and information costs. The basis of this increased stability may be important in explaining the inability of empirical workers to find anything but a negatively sloping Phillips curve. On the other hand, the possibility of policy error is magnified, and this leads to instability. Second, the existence of a sector that pays a wage premium increases the amount of voluntary unemployment in the system and causes a redistribution of income from those not employed to those employed in the high wage sector. This type of unemployment is theoretically similar to the unemployment which arises in "dual labor" market theories. The market mechanism embodied in the dual labor market is currently popular in describing developed as well as underdeveloped economies.[5] Third, noncompetitive factors are shown to have an important dynamic influence upon inflation.

The outline of the paper is as follows. Section I develops a theory of the administered, or noncompetitive, firm. Section II introduces the competitive sector. Section III aggregates the results of the previous two sections into a single macro-economic model, and Section IV analyzes the short- and long-run dynamic behavior of this model. Section V, a summary, discusses the theoretical and policy implications of the model.

I. The Administered Sector

Nature of the Administered Firm

A maintained assumption of this paper is that firms differ in the discretion they can exercise in setting price. These differences are due to factors such as the firm's technology (as it influences the shape of its cost curves), the size of the market, and, in general, all factors that help to determine the number of firms in the industry and the degree of constraint on further entry. For expositional simplicity we divide the economy into two polar cases, those firms with pricing discretion (the noncompetitive or administered sector) and those firms that are purely price takers (the competitive sector).

In the industries with price discretion

[5] For a discussion of dual labor market theories in underdeveloped economies see W. Arthur Lewis, Michael Todaro, and John Harris and Todaro. Similar types of models for developed economies have been investigated by Peter Doeringer and Michael Piore and Bennett Harrison.

it is likely that there is some price structure, different from the price structure that would prevail if the sector were competitive, that maximizes each firm's profits.[6] Once agreement within an industry is reached on a price structure, it is then clearly both costly, in terms of agreeing on a new price structure, and risky to alter the structure. The primary risk, of course, is that of a loss of monopoly profits from a breakdown in the informal price agreements. It follows that from the industry's point of view, it is undesirable to have prices change with the frequent short-run changes in demand or cost conditions since such changes would open the possibility of disagreement and threaten the structure in an unpredictable fashion.[7]

As a consequence, a crucial component of noncompetitive, or what we will hereafter call administered pricing, is that it exhibits a certain amount of price stability in the face of variations in market conditions. To represent this we assume that the price decision is made only at the beginning of a finite planning period. During the planning period prices then either remain constant or change according to a set strategy that is part of the initial price decision. (For simplicity, our analysis concentrates on that case where prices are constant over the planning period.)

In order to preserve the industry price structure, it is necessary for the firms to develop an agreed upon method of signaling when prices should change in response to changing demand and cost conditions. Since price changes are costly and, if erratic, carry the risk of substantial loss, such a device must signal both infrequently and reliably. A traditional method for achieving this reliability is to base prices on a markup on certain standard costs that are both important in total industry variable costs and nearly identical for all firms in the industry. Thus, prices are often based on a markup on wages. Unions can be helpful if industry-wide settlements are the rule although the mere existence of a long-term wage contract is not sufficient to ensure the desired wage stability.[8] For a long-term wage contract to have operational significance, it is necessary that the contract include a wage premium that will insulate the firm from short-run changes in the economy-wide demand for labor.[9] If this were not

[6] A major reference on the existence and behavior of a noncompetitive sector is by Frederick Scherer. The notion that each firm maximizes profits is, of course, ambiguous in the oligopoly context. There are many approaches to the oligopoly problem. Most, however, are compatible with our analysis. It should also be noted that a price structure can refer to both interfirm prices and interproduct prices. In the first case, firms may not all have the same prices; however, differentials are agreed upon. The more traditional price structure refers to the price list for the various products that the firms produce.

[7] The stability of administered firm prices in the face of fluctuations in product demand is discussed by Otto Eckstein and Gary Fromm. The debate over the question of whether or not administered prices are stable dates back to the 1930's. Scherer concludes that the evidence does tend to support those who suggest that administered prices are stable. More recently, George Stigler and James Kindahl have questioned this conclusion. They contend that the empirical support for stable administered prices is based on wholesale price indices, which are seller list prices, and argue that a series created by observing the actual buying price would show a great deal more cyclical variation. This is largely due to price shading during recessions. The Stigler-Kindahl argument does not necessarily weaken the case of the administered sector presented in this paper. First, Stigler and Kindahl show only that administered prices are not stable; they do not answer the more important question (for our model) as to whether those prices are as relatively unstable as competitive prices. Secondly, it is likely that administered industries do not simply establish a single list price. Rather, they establish a trading range which has the list price as a marker. Some price shading in this framework would be within the bounds of the price agreement of the administered firms. This could account for the Stigler-Kindahl findings and would not be in contradiction to the establishment of a fixed pricing *strategy*.

[8] The term industry-wide settlements includes the case where a single contract for an industry is negotiated and the case where spillover effects link one contract in an industry to another.

[9] For an earlier and somewhat different view of the

the case, wage rates would have to be adjusted frequently to reflect market forces, and the advantage of stable administered prices based on a markup on fixed standard costs would be lost. On the other hand, with a wage premium the administered firm hires workers off a queue. Fluctuations in product demand, and thus in the derived demand for labor, cause flunctuations in numbers hired off the queue but not in the size of the money wage rate offered.[10]

The Wage and Price Decision

For simplicity and in order to concentrate on the inflation problem we assume that all variable costs are labor costs in both the administered and the competitive sectors and that over the relevant production range changes in output are simply proportional to employment. One consequence of this assumption is that since the competitive real wage, ω, will equal labor's marginal product (in the competitive sector), ω will be constant.[11] Since wages and prices change together, we also assume that the firm simultaneously makes both a wage and a price decision at the beginning of a fixed planning period, at the time T, and maintains both until the start of the next period, at time T+1.[12]

The administered firm operates under a supply and demand (for labor) constraint that, for any given moment within the planning period, τ, may be written

$$\text{(1a)} \quad L \leq L^s\left(\frac{w_T^a}{w_{T+\tau}^c}\right), \qquad 0 \leq \tau < 1$$

and

$$\text{(1b)} \quad L \leq L^d\left(\frac{p_T^a}{p_{T+\tau}^c}\right), \qquad 0 \leq \tau < 1$$

where L is the actual employment of the administered firm, w_T^a and p_T^a are its respective wage and price decisions made at time T and lasting until T+1, and $w_{T+\tau}^c$ and $p_{T+\tau}^c$ are the competitive wage and price levels at time T+τ, respectively.[13] The administered firm regards w^c and p^c as given. The first inequality denotes the labor supply limitation on hiring, and the second constraint asserts that the firm would not hire labor in excess of the amount required to produce the current product demand L^d.[14]

impact of union contracts on wage determination see the article by Eckstein and Thomas Wilson. The interaction between noncompetitive elements in product and labor markets is developed by John Dunlop (1944), (1957).

[10] The argument may be restated to emphasize that administered firms desire an assured supply of labor. This is similar to the model of administered firm behavior suggested by John Kenneth Galbraith. There, an assured labor supply as well as an assured supply of all inputs (and product demand to the extent that it is possible) is desired in order to reduce uncertainty. Galbraith interprets this as based on nonprofit maximization. We suggest that profit maximizing behavior is still relevant, but must be altered by the explicit recognition of uncertainty.

[11] The assumption of an exogenous real wage is made not only for simplicity, but also to stress the distinction between our findings and Patinkin-like disequilibrium analysis. The movement of real wages over the cycle is of great interest, however, its solution involves a more complex development of the disequilibrium behavior of the competitive sector. See, for example, Don Patinkin, R. Clower, Robert Barro and Herschel Grossman and E. Roy Weintraub and Sidney Weintraub. The marriage of our work with these competitive disequilibrium models is a difficult and distinct project.

[12] In a recent paper, George Akerlof develops a model of an economy with two noncompetitive firms where firm 1 sets its wage and price at time t, t+2, t+4, . . . , while firm 2 sets its wage and price at t+1, t+3, t+5, ... Although there are important differences, his model is the closest to our own of any in the literature.

[13] These can be interpreted either as stock or flow constraints. Since our analysis will hold in either case, we will not be explicit.

[14] This is, of course, an assumption rather than a true constraint and serves primarily to abstract from inventory accumulation. The assumption is made solely to facilitate the analysis. A stock of inventories has a role similar to that of the labor queue. Each is useful in avoiding a customer queue, and an administered firm is likely to maintain both inventories and a labor queue. An unexpected increase in the product demand would, therefore, lead to a reduction in inventories and queue size.

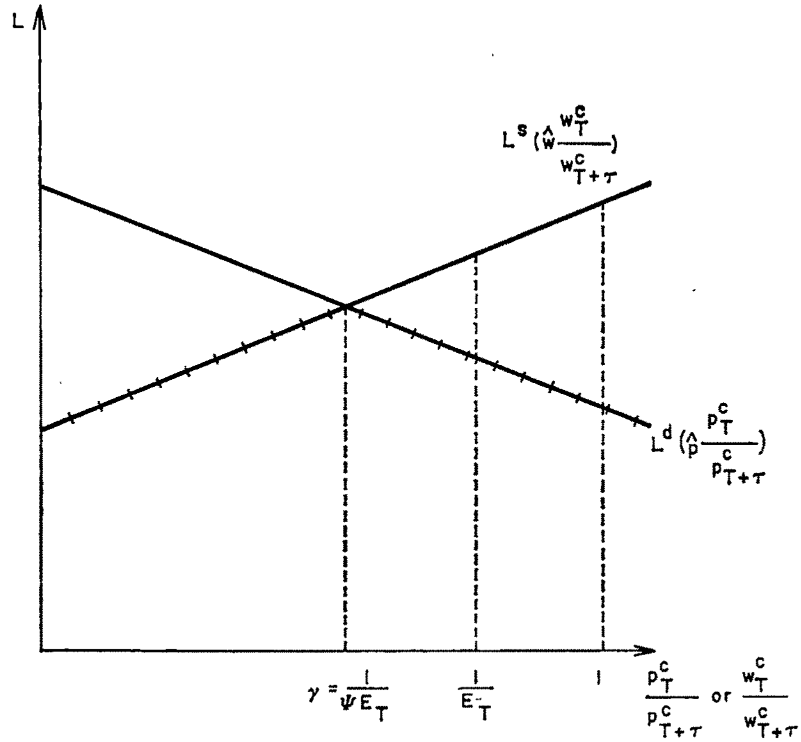

FIGURE 1

The labor demand function of the administered firm varies inversely with its relative price p^a/p^c, where p^c is used as a proxy variable for the overall price level.[15] The existence of a positive cross-price elasticity between the representative administered firm and other firms in the administered sector and/or firms in the competitive sector can justify the downward slope. The labor supply function depends positively on the administered firm's relative wage, w^a/w^c, because of the short-run immobility of labor.

Denoting the relative wage and price by $\hat{w} \equiv w^a_T/w^c_T$ and $\hat{p} \equiv p^a_T/p^c_T$, equations (1a) and (1b) may be rewritten as

$$L \leq L^s\left(\hat{w} \cdot \frac{w^c_T}{w^c_{T+\tau}}\right) \tag{1a'}$$

and

$$L \leq L^d\left(\hat{p} \cdot \frac{p^c_T}{p^c_{T+\tau}}\right) \tag{1b'}$$

The supply and demand functions in constraints (1a′) and (1b′) are depicted in Figure 1. The horizontal axis contains either $p^c_T/p^c_{T+\tau}$ or $w^c_T/w^c_{T+\tau}$; the two are equal by the constancy of the real wage. The area below the thatched line displays the constraints of (1a) and (1b).

At the beginning of each planning period the firm sets w^a_T and p^a_T. In so doing it fixes $\hat{w}$ and $\hat{p}$, the slopes of the demand and supply curves in Figure 1, and thus their intersection point γ. To the left of γ, customers queue, and to the right of γ, workers queue. At the beginning of the

[15] It might seem better to use an average administered sector price or an industry price as the denominator of the relative price term, but as will be seen later, the use of the competitive price does provide a satisfactory proxy for the relative price term and greatly simplifies the model.

planning period, τ equals zero and the administered firm is at the unity point on the horizontal axis. As τ varies from zero to unity, $p^c_T/p^c_{T+\tau}$ and $w^c_T/w^c_{T+\tau}$ may change, thus altering the position on the horizontal axis. The firm's optimal choice of γ is determined by the firm's expected rate of inflation and its presumed evaluation of profits when either workers or customers are forced to queue. If the expected rate of inflation, $E_T \equiv$ expected (p^c_{T+1}/p^c_T), were certain the firm would set $\hat{w}$ and $\hat{p}$ (the slopes of the supply and demand curves, respectively), so that $\gamma = 1/E_T$. When the forecast, E_T, is not certain, the relative cost to the firm of worker and customer queues is important in determining γ. If the realized rate of inflation is less than E_T, then workers queue, and the profit loss to the firm consists of the excess wage premium. On the other hand, when the realized inflation goes beyond E_T, the profit loss is in excess of the current profit opportunity loss of the low price. The reason for the extra loss is that disappointed customers who are forced to queue may not remain as customers in the future. The reduction in current accounting profits, therefore, understates the loss in discounted lifetime profit. Hence, the opportunity loss from underestimating the rate of inflation exceeds that of overestimating, and the risk-averse firm will pay a wage premium. This safety factor is measured by the term $\Psi > 1$ and the firm sets $\gamma = 1/E_T\Psi$.

To summarize, even though the firm expects an inflation rate of E_T, risk aversion will lead it to set its market clearing point γ so as to have a worker queue if expectations are realized. It does this to reduce the probability of having a customer queue which it views as being more costly than a worker queue.[16]

It can be shown formally that the above model of the administered firm leads to wage and price equations of the form:[17]

$$w^a_T = \phi\Psi E_T w^c_T \tag{2a}$$

$$p^a_T = \mu\Psi E_T p^c_T \tag{2b}$$

The terms $\phi\Psi$ and $\mu\Psi$ represent the markup of the administered firm since, if they were equal to unity, the administered wage and price would be equal to the competitive wage and price adjusted for the expected rate of inflation over the planning period. The basic noncompetitive features of the product and labor markets of the administered firms are represented by μ and ϕ. The variables μ and ϕ are (increasing) functions of aggregate demand and may be greater or less than unity depending upon the exact shapes of the supply and demand functions the firm faces.[18]

[16] An additional reason for the administered firm to pay a wage premium stems from the observation that the supply curve of labor is likely to be more elastic than the demand curve of labor. The firm belongs to an oligopolistic industry and is a participant to an administered pricing scheme where relative prices among firms in an industry are largely constant. These features decrease the elasticity of the product demand and thus the derived demand for labor. On the other hand, the firm may be in a perfectly competive labor market. In this case as soon as $w^c_{T+\tau} > w^a_T$ its labor supply leaves for the competitive sector, and the profits of the firm fall to zero. To avoid this the administered firm will establish a worker queue by setting $\Psi > 1$. More generally, labor supply may be sufficiently more elastic than labor demand and the argument will still be valid.

[17] The formulas are derived in our 1972 paper. Markup formulas also play a central role in the macromodel developed by S. Weintraub.

[18] If ϕ is small enough, $\phi\Psi$ may be below unity so that the noncompetitive firm would not pay a wage premium over the competitive wage. (If one assumes that the competitive and noncompetitive firms produce different products, then the notion of a price premium is not well defined and, therefore, does not play an important role in the model. Since we are assuming homogeneous labor, however, the notion of a wage premium is well defined.) The question as to whether noncompetitive firms pay a wage above the competitive wage, however, is largely empirical and should not be confused with the fact that the administered firm always pays a premium over the wage necessary to clear its own labor market. Since there is considerable evidence that noncompetitive firms do pay higher wages than competitive firms, we will assume that this is the case throughout the re

In the above discussion, the justification for the behavioral assumptions of the administered sector is based on decision variables under the control of the administered firm. The model, however, should be interpreted as being relevant to a broader group of industries than those traditionally recognized as having very high concentration ratios. First, similar results may be obtained for industries where the decision variables are, at least partially, controlled by labor unions. The results above suggest that the firms set their wage and price strategies at the beginning of a planning period (maintain a fixed strategy over that period) and pay a wage premium. Clearly, these same features are desired by labor unions. Traditionally, unions are viewed as attempting to achieve a wage for their members which is greater than the wage dictated by market conditions. Furthermore, since contract setting is a costly process, unions do not seek continuous renegotiation of contracts; rather, they prefer contracts which are fixed for a period of time. Secondly, the dichotomy of firms as competitive or noncompetitive is not critical. More realistically, industries may be classified along a continuum with respect to their noncompetitive features. The interaction among firms along the continuum will lead to the same qualitative macro-economic behavior that is described below for the dichotomous case.

II. The Competitive Sector

In the competitive sector, the wage and price adjust continuously to clear the market.[19] The assumption of instantaneous reaction in the competitive sector is made solely to concentrate attention on the economic effects that arise when a noncompetitive sector exists along with a competitive sector. The recent neoclassical literature on transactions costs and other frictions in a competitive economy could be built into our competitive sector. Indeed, it is suggested below that any lags of adjustment that may occur will be additive to the institutional lags of the noncompetitive sector.[20]

Assuming that the aggregate labor supply is fixed, the supply to the competitive sector may be written as a residual and is given by

$$\bar{L} - S^a\left(\frac{w^a}{w^c}\right) \tag{3}$$

where $\bar{L}$ is the (assumed) constant aggregate supply of labor, and $S^a(w^a/w^c)$ is the labor supply to the administered sector written as a function of relative wages. The derived demand for labor in the competitive sector is assumed to be proportional to aggregate demand, denoted m. On the assumption that the competitive labor market is continually in equilibrium we have

$$km = \bar{L} - S^a\left(\frac{w^a}{w^c}\right) \tag{4}$$

where $k>0$ is the constant proportionality factor in the labor demand equation.[21] Equation (4) indicates that the level of aggregate demand is uniquely related to the relative wage.

maindor of the paper. The qualitative results of later sections do not depend upon this assumption to any significant extent.

[19] As in the section on the administered firm, we assume that the capital stock, technology, and the real wage are fixed.

[20] See, for example, Charles Holt and Dale Mortensen for a discussion of the labor market mechanism in a competitive economy.

[21] In a model with two broad classes of output it is reasonable that the output of both sectors should be strongly superior goods in the sense that a rise in the level of real balances would require an extreme price shift to prevent aggregate demand for the output of either sector from rising. Furthermore, if one conceives of the noncompetitive sector as being composed primarily of manufacturing industries and the competitive sector as being composed primarily of service industries, then the cross-price elasticity between the two sectors is likely to be close to zero.

III. The Macromodel

In this section we will put together the pieces constructed in Sections I and II into a single macromodel. Since the competitive sector has been developed in aggregate form, it only remains to aggregate the administered firms into a single administered sector. We assume that the administered firms all have planning periods of identical length but that the initial point is different for each. If the administered firms have initial decision points distributed uniformly over the interval between T−1 and T, and if all firms are identical, then the administered wage and price indices may be represented by

$$w^a(\mathrm{T}) = \int_{\mathrm{T}-1}^{\mathrm{T}} w_\tau^a d\tau \tag{5a}$$

and

$$p^a(\mathrm{T}) = \int_{\mathrm{T}-1}^{\mathrm{T}} p_\tau^a d\tau \tag{5b}$$

The principal aggregation problem is to find an expression for aggregate unemployment in the economy as a function of the demand proxy variable, m, and the wage and price variables. Since we have assumed that the competitive sector labor market clears continuously, all of the system's unemployment is found in the labor queues of the administered sector. This is, of course, not the only type of unemployment in the economy, and we are abstracting away from the other forms in order to concentrate on the implications of our two-sector labor market model.

The worker can either work in the competitive sector or seek work in the administered sector. The recent literature on job search strongly suggests that the workings of the labor market and the time constraint of a 24-hour day makes it unlikely that a worker can simultaneously search for a job in the administered sector while working in the competitive sector. At any rate, to do so would be costly and this is really all that is required for our analysis.[22]

Figure 2 displays the aggregate demand and supply curves for labor in the administered sector as a function of the relative wage for a given level of aggregate demand, m. As with the product demand in the competitive sector, we assume away relative price effects (due to the level of aggregation), and, given homogeneity, this allows us to write the sector's demand for labor as $D^a(p^a/p^c,\ m)=\beta m$. The curve $S_f^a(w^a/w^c)$ is the full employment supply function that gives the number of workers who would be willing to work in the administered sector if the probability of finding employment in the sector were equal to unity. For $w^a/w^c>1$, it asymptotically approaches the aggregate labor supply $\bar{L}$. It is not coincident with $\bar{L}$ because of the mobility costs associated with moving between sectors. For a relative wage equal to $(w^a/w^c)_0$, the amount of labor hired in the administered sector is $D^a=\beta m$. The horizontal distance between D^a and S_f^c at $(w^a/w^c)_0$, however, does not give the unemployment in the system; as long as unemployment is positive (and thus the probability of find-

[22] The general view in the search literature is that a worker cannot apply once-and-for-all for a job with a firm in the high wage sector and then, while waiting to be called for employment, hold a job in the low wage sector. Hirings are made from the pool of active job applicants; that is, when a vacancy develops, the first "qualified" individual to come into the personnel office is hired. This is less costly to the firm than attempting to trace back old applicants who may have applied first for the job. Indeed, the older the date of application, the less likely it is that the applicant can be found or will still be interested. Consequently, it is the individual who spends his day visiting personnel offices, who is likely to be hired in the high wage sector. In fact, the worker is not constrained to join the queue of a single administered firm; rather, each worker can search among a number of firms. As a consequence, the notion of unemployment is well defined only for the administered sector as a whole and not for individual administered firms.

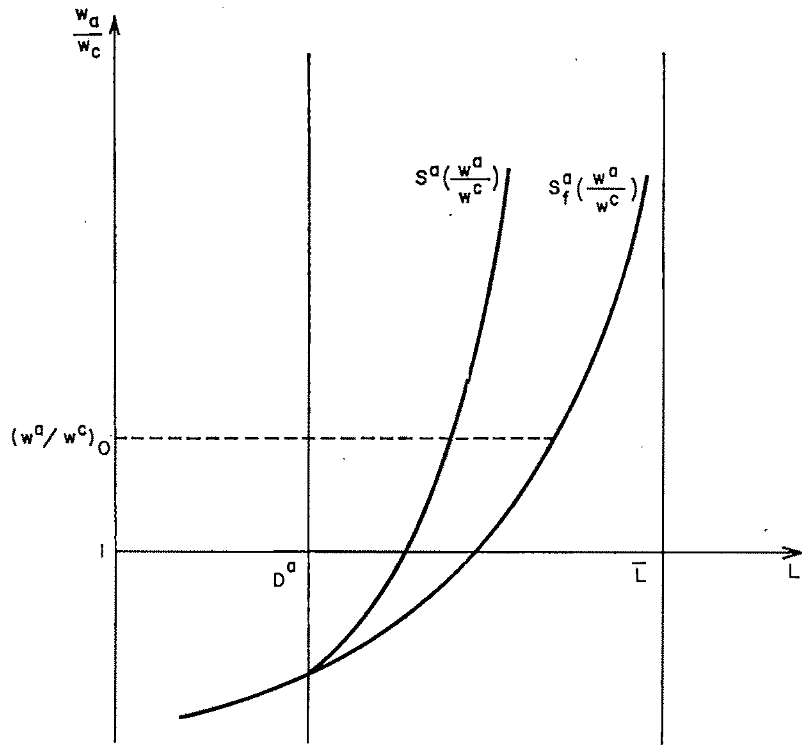

FIGURE 2

ing work is less than unity), the actual supply function to the administered sector is to the left of S^a_f.

The position of the observed (disequilibrium) supply function to the administered sector S^a depends upon two conflicting forces. Namely, as relative wages are increased, the reward for choosing the administered sector rises, but to the extent to which the ratio of S^a/D^a rises, so does the probability of not being employed. The observed supply function is bounded on the right by S^a_f, where the discouraged worker effect is zero, and on the left by D^a, since on D^a the probability of being hired is equal to unity.[23] Thus, S^a will be determined as the solution to an equation of the form:

$$S^a = S^a\left[\frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}}, \frac{U}{D^a}\right] \tag{6}$$

where $U = S^a - D^a$ is the amount of unemployment in the system.[24] Assuming

[23] The supply function S^a is observable only where its slope is greater than the slope of the demand function. If this were not the case, unemployment would fall as the relative wage was increased, and to the extent that the administered sector was aware of the shape of S^a, it would never increase its relative wage into this region. Notice that if $D^a \to 0$ as the relative wage rose then S^a could actually fall with rising relative wages. The workings of the supply mechanism with demand shifts are obvious. An increase in real balances shifts the administered sector demand function to the right, and if relative wages are held constant, this will increase employment in the sector. The increase in employment increases the probability of being hired and this, in turn, shifts the supply function S^a towards the full employment supply S^f.

[24] In this model the existing unemployment is not strictly search unemployment in the sense that we do not have heterogeneous workers searching among heterogeneous jobs and there is no lack of information as to the probability of a worker being hired in the ad-

that this equation may be solved explicitly for U and approximated by a linear form, we have

$$(7) \qquad U \cong e\frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}} + f - hD^a$$
$$= e\frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}} + f - h\beta m$$

where $e, f > 0$, and $0 < h < 1$. The parameter k may differ from unity because of the influence of the change in the probability of being hired upon the supply of labor. For simplicity, we will assume that h is constant.

The unemployment described by equation (7) is similar, in a theoretical sense, to the unemployment that arises in a dual labor market setting which contains a high wage sector and a relatively low wage, market clearing sector. Although the dual labor market has traditionally been viewed as relevant to underdeveloped economies, current empirical research suggests that it is also descriptive of developed economies such as that of the United States.[25] As mentioned above, however, this paper assumes market clearing in the competitive sector solely to concentrate on the effects introduced by the interaction between the two sectors. The effects of this interaction on wage determination and inflation, however, are not sensitive to the precise assumptions concerning market clearing.

For reference, the complete macromodel is written below. The wage and price equations are

$$(5a) \qquad w^c(\mathrm{T}) \equiv \int_{\mathrm{T}-1}^{\mathrm{T}} w^a_\tau d\tau$$

and

$$(5b) \qquad p^c(\mathrm{T}) \equiv \int_{\mathrm{T}-1}^{\mathrm{T}} p^a_\tau d\tau$$

where the administered markups are given by

$$(2a) \qquad w^a_\tau = \phi(m)\Psi E_\tau w^c_\tau$$

and

$$(2b) \qquad p^a_\tau = \mu(m)\Psi E_\tau p^c_\tau$$

Aggregate unemployment is given by

$$(7) \qquad U = e\frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}} + f - h\beta m$$

Using (7), the competitive market clearing equation may be written as

$$(4') \qquad cm = \left\{\bar{L} - \left(e\frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}} + f\right)\right\}$$

where

$$c \equiv k + (1-h)\beta > 0$$

Equation (4′) implies that the relative wage structure is a function of aggregate demand alone:

$$(8) \qquad \frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}} = \frac{(\bar{L} - f) - cm}{e}$$

Hence, unemployment becomes a function of aggregate demand, i.e.,

$$(9) \qquad U = e\frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}} + f - h\beta m$$

ministered sector. The assumptions of homogeneous workers and jobs and perfect information on the probability of being hired are made only to simplify the analysis. The model, however, may be extended—without altering the conclusions of the paper—by explicitly introducing search considerations.

[25] A component of unemployment in the dual theories arises because the price of leisure is greater than the wage in the low wage sector, but lower than the wage in the high wage sector. Hence, workers who are unemployed for a prolonged period eventually leave the labor force. In this paper, the size of the labor force is assumed to be exogenous so that unemployed workers are assumed to prefer work in the low wage sector than to be out of the labor force. This assumption, which is made to simplify the analysis, can easily be altered. For a still more general theory one could also introduce heterogeneous workers and jobs as discussed in fn. 24.

$$= e\left[\frac{(\bar{L} - f) - cm}{e}\right] + f - h\beta m$$
$$= \bar{L} - (c + h\beta)m$$

IV. Steady-State Dynamics

Constant Expectations

In this section we investigate the manner in which the two sectors interact in the macromodel. We shall find that the steady-state dynamics of the model can describe many empirically observed phenomena. It is easiest to begin by analyzing the case where expectations are constant, $E_t = E$, and where competitive wages and hence prices are growing at a constant rate of growth ξ, i.e.,

$$(10) \qquad Dw_T^c = Dp_T^c = \xi$$

where $Dx \equiv (1/x)dx/d\tau$. From the definitions of the aggregate wages and prices (5) and the markup equations (2) we have

$$(11) \quad w^a(\mathrm{T}) = \int_{\mathrm{T}-1}^{\mathrm{T}} w_\tau^a d\tau = \int_{\mathrm{T}-1}^{\mathrm{T}} \phi\Psi E w_\tau^c d\tau$$
$$= \phi\Psi E g(\xi) w_t^c$$

where

$$g(\xi) \equiv \int_{\mathrm{T}-1}^{\mathrm{T}} e^{-\xi(\mathrm{T}-\tau)} d\tau = \frac{1}{\xi}(1 - e^{-\xi})$$

Hence, relative wages and prices are given by

$$(12a) \qquad \frac{w^a(\mathrm{T})}{w_\mathrm{T}^c} = \phi(m)\Psi E g(\xi)$$

and

$$(12b) \qquad \frac{p^a(\mathrm{T})}{p_t^c} = \mu(m)\Psi E g(\xi)$$

Since $g(\xi)$, the growth markup, declines monotonically in ξ, the wage and price premium of the administered sector varies inversely with the rate of change of wages and prices. To understand this result, suppose that the system is originally in a dynamic equilibrium with wages and prices increasing at the rate ξ in both sectors. Let the system be disturbed by an increase in Dw_T^c to $\xi' > \xi$. Since the entire competitive sector adjusts continuously, ξ' is the rate of wage change for all competitive firms. The administered sector, however, adjusts with a lag; the only administered firms that can adjust immediately to the change are those at the beginning of a new planning period. The result, in steady-state equilibrium, is a narrowing of the wage structure. Furthermore, as long as expectations are unchanged (an assumption that we will drop in the next section), the wage structure will remain indefinitely in the narrowed position given by the equilibrium equations (12a) and (12b). Although the representative administered firm "catches up" with the competitive sector at the beginning of its planning period, the firm plans only an inflation markup of E for the planning period. Consequently, the larger is ξ', given E, the further behind the firm will be at the end of the planning period. (This does not mean that $w^a(\mathrm{T})$ necessarily falls behind w_T^c. That result would depend upon the difference between Dw_T^c and E_T in relation to the markup $\phi\Psi$.) Since the economy, at any point in time, consists of administered firms at different stages of their respective planning periods, it follows that the greater the growth rate, the narrower the wage structure.[26]

The above analysis is useful in tracing out the effects of changes in aggregate demand or real balances on the rate of inflation and unemployment, as the economy moves across steady states with

[26] For a further discussion of the mechanism through which the wage structure varies over the cycle, see Wachter (1972). Evidence that the wage structure narrows when aggregate demand rises (and thus unemployment declines) also may be found in the Wachter paper.

constant expectations. Given our assumptions about price elasticities, an increase in m appears as an increase in demand to both sectors. For the high wage sector the immediate adjustment means an increase in sector employment and thus a decrease in the size of the queue. If the competitive sector also is to meet the increase in demand, it must attract labor from the queue of the high wage sector. As a result, it must increase its relative wage. Differentiating (8) with respect to m, we obtain

$$\frac{\partial(w^a(\mathrm{T})/w^c_{\mathrm{T}})}{\partial m} = -c/e < 0$$

that is, to allow increased hiring in the competitive sector, the wage structure narrows with an increase in real demand. Clearly, however, this narrowing cannot be brought about simply by a once-and-for-all increase in the competitive wage level since such a wage increase would be matched by firms in the administered sector. The only way for the low wage firms to succeed in raising their relative wage is to increase their *rate* of wage change Dw^c_{T}. The mechanism through which an increase in Dw^c_{T} or ξ narrows the wage structure was described above.

To formally verify that an increase in demand increases the steady-state rate of inflation, we differentiate (12a) with respect to m,

$$(13)\quad \Psi E\left(\phi'(m)g(\xi) + \phi(m)g'(\xi)\frac{\partial \xi}{\partial m}\right) = \frac{\partial}{\partial m}\left(\frac{w^a(\mathrm{T})}{w^c_{\mathrm{T}}}\right) = -\frac{c}{e} < 0$$

and solve for

$$(14)\quad \frac{\partial \xi}{\partial m} = \frac{-\frac{c}{e} - \Psi E\phi'(m)g(\xi)}{\Psi E\phi(m)g'(\xi)}$$

Since the markup increases with increases in demand, $\phi'(m)>0$, and since $g'(\xi)<0$, we have $\partial\Psi/\partial m>0$.[27]

The impact of changes in m on unemployment can be obtained by differentiating (9) with respect to m. It is obvious that an increase in real balances or aggregate demand causes a decrease in unemployment.

The implications of an increase in aggregate demand may be summarized in the following manner. Assume the system is originally in equilibrium with $\xi=E$. For both sectors the increase in aggregate demand causes a shift in the derived demand for labor. The high wage sector can satisfy its increased demand by drawing upon its labor queue, that is, reducing unemployment without increasing its rate of wage change. The low wage competitive sector, on the other hand, needs to increase its wage offer relative to the high wage sector in order to attract the additional workers from the unemployment pool of the high wage sector. The increase in relative wages is achieved for constant expectations by increasing Dw^c_{T}. Furthermore, the larger the increase in aggregate demand, the greater the increase in the rate of inflation, the narrower the wage structure, and hence, the smaller the remaining unemployment.[28] This inverse relationship between inflation and unemployment is the short-run Phillips curve displayed in Figure 3.[29]

Realized Expectations

The Phillips curve is a steady-state concept, drawn for a particular level of expectations. Friedman and Phelps have

[27] The assertion that $\phi'(m)>0$ is an intuitively clear result and will be assumed below.

[28] Notice that since a given wage structure is associated with a given unemployment rate, a low unemployment rate means a high rate of aggregate wage and price change, but not a constantly changing relative wage.

[29] The convexity of the Phillips curve is assumed.

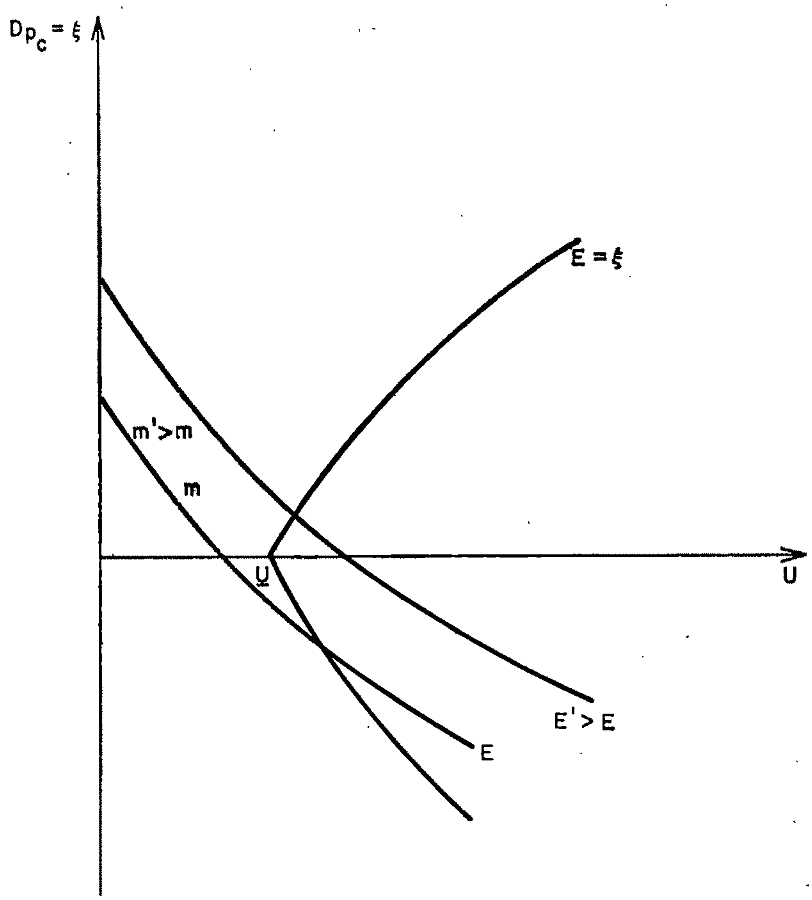

Figure 3

argued that the curve will shift vertically upward by 1 percent for every 1 percent increase in expectations. Suppose on the Phillips curve of Figure 3 the point (U, ξ) had the property that expectations were realized, i.e., the actual rate of inflation ξ was the rate expected. If a rise of $\Delta\xi$ in expectations caused the curve to shift upward by $\Delta\xi$, then $(U, \xi+\Delta\xi)$ would be the point on the new curve where expectations were realized, and there would have been no alteration in unemployment, U (hence, m could remain constant). In other words, the fully anticipated inflation has had no real effects, and if we connected all the points at U, we would have a vertical long-run Phillips curve. In our model this is not the case and inflation, even when fully anticipated, will have real effects.[30]

Since expectations are realized, in continuous time E_T will be some function of the actual rate, and for the present we let

$$E_T = E\{(p^c_{T+1/2})/p^c_T\}$$
$$= p^c_T/p^c_{T-1/2} = e^{\xi/2}$$

justifying this assumption below. Substituting this into the wage structure equation (12a) we obtain

[30] This is a bit ambiguous. More precisely, the inflation has no real effects if aggregate demand is held constant, but then expectations cannot be realized at all rates of growth. This is discussed below.

$$(15)\qquad \frac{w^a(\mathrm{T})}{w_{\mathrm{T}}^c} = \phi\Psi e^{\xi/2}g(\xi) \equiv \phi\Psi h(\xi)$$

where $h(\xi)\equiv e^{\xi/2}g(\xi)$ is the growth markup with realized expectations. Unlike $g(\xi)$, $h(\xi)$ is an increasing function of the growth rate (for $\xi>0$), and with realized expectations the wage structure widens with increases in the rate of wage and price inflation.[31]

The response of the system to changes in aggregate demand and the nature of the long-run Phillips curve may now be identified. From (14) we have

$$(16)\qquad \frac{\partial\xi}{\partial m} = \frac{-\dfrac{c}{e} - \Psi\phi'(m)h(\xi)}{\Psi\phi(m)h'(\xi)} < 0$$

since $\phi'(m)>0$ and $h'(\xi)>0$. That is, when expectations are realized, an increase in real balances is associated with a lower rate of wage and price inflation. As a result, since an increase in real balances (or aggregate demand) reduces unemployment, the long-run Phillips curve (Figure 3) has a positive slope, i.e.,

$$(17)\qquad \frac{\partial\xi}{\partial U} = \frac{\partial\xi}{\partial m}\frac{\partial m}{\partial U} > 0$$

The emergence of an upward sloping long-run Phillips curve has its roots in the assumption that the administered firm finds a customer queue more costly than a worker queue or, alternatively (where the high wage sector is a unionized sector), that the union desires a wage premium for its members. This implies that the firm sets its wage and price decision so as to have a worker queue over the bulk of the planning period, i.e., the full employment point, γ of Figure 1, is reached near the end of the period. To see heuristically that this implies an upward sloping Phillips curve, suppose that the actual and realized rate of inflation increases. Assume that at the initial rate of inflation the firm would be at point a, in Figure 4, at the end of the planning period, whereas at the higher rate of inflation it would be at point b at T+1. If the firm always desires a worker queue, γ is set at the end of the period and an increase in ξ causes firms to increase their relative wage and thus to alter L^D and L^S so that they intersect at b rather than at a in Figure 4. Thus, if a firm desires to maintain a worker queue throughout the planning period, an increase in the rate of inflation forces the firm to increase its relative wage and hence the average number of workers on the queue (i.e., the number of unemployed workers) throughout the period also increases. It is shown above, algebraically, that if firms look roughly to the middle of the period, i.e., $E=e^{\xi/2}$, this is sufficient to override the growth markup, $g(\xi)$, making $h(\xi)$ positive and hence yielding an upward sloping Phillips curve. Since firms look more to the end than to the beginning of the period, they set $E>e^{\xi/2}$, and the upward sloping curve holds *a fortiori*.

In summary, the markup $g(\xi)$ indicates the extent to which the administered sector lags behind the competitive sector. Consequently, as the rate of inflation, ξ, increases and $g(\xi)$ declines, the wage premium narrows. When the increase in ξ is anticipated, though, administered firms respond by increasing their wage markup. This offsets the narrowing of the premium induced by the lag of the administered sector. The net result is an increase in the wage differential and, hence, in unemployment.

[31] Letting $h(x)=(e^x-e^{-x})/x$, sign $h'(x)=$ sign $\{(x-1)e^x+(x+1)e^{-x}\}$. Since $h'(0)=0$ and $d/dx[(x-1)e^x+(x+1)e^{-x}]=x(e^x-e^{-x})$ for $x>0$, we must have $h'(x)>0$, and for $x<0$, $h'(x)<0$. In what follows we will consider only the case where $\xi>0$. For the alternative case, see the discussion at the end of this section.

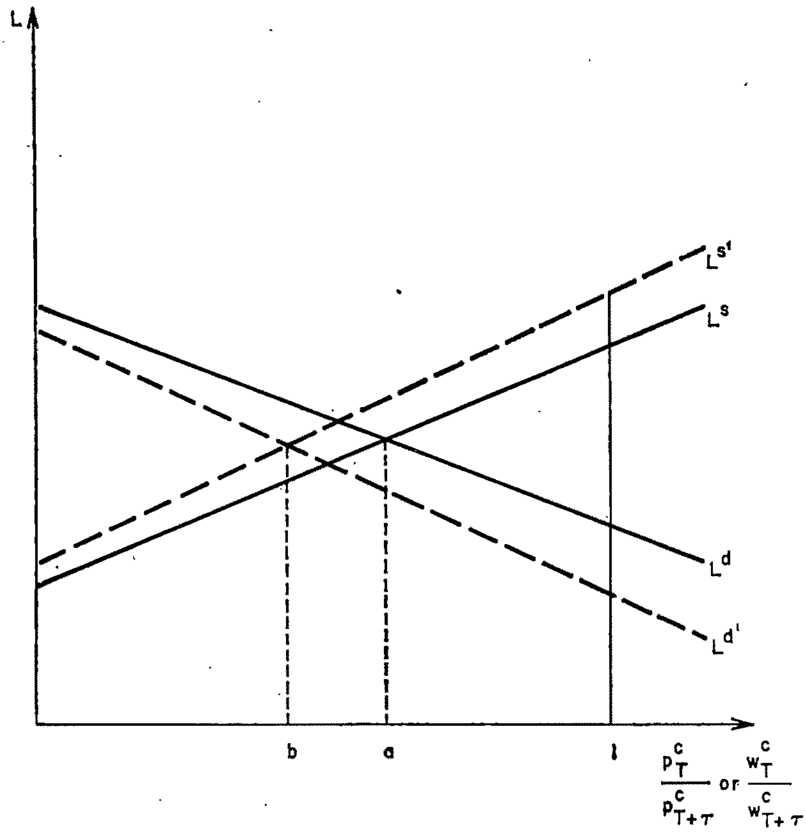

FIGURE 4

In the case where the economy is deflating, the above arguments are reversed. Now the firm will attempt to set the full employment point γ (perhaps to the right of unity) near the beginning of the planning period, allowing the deflation to carry it into a worker queue region over the bulk of the period. Consequently, the deflation markup will be close to unity, and $h(\xi)$ will be close to $g(\xi)$. The signs of (16) and (17) will now be reversed, and the long-run Phillips curve will be downward sloping (see Figure 3). This implies that there is a minimal level of unemployment, U in Figure 3, which can be attained by aggregate demand policies alone when expectations are realized. Attempts to achieve lower unemployment than U through aggregate demand policies, cannot succeed in the long run.[32]

A caveat is necessary in concluding this section. Although we have derived a so-called long-run Phillips curve, the notion of long-run equilibrium in an economy with noncompetitive elements is ambiguous. In particular, it is possible that institutional features may change in the long run in response to economic variables.

[32] Although the c-shaped long-run Phillips curve in the above analysis is based on the assumed attitude of the administered firm towards a customer queue, other reasonable behavioral assumptions could also lead to the same result. For example, if administered firms view demand as being more uncertain when prices and wages are changing rapidly rather than when they are changing slowly, the safety factor, Ψ, would become a function of ξ so as to result in a c-shaped Phillips curve.

For example, the length of the planning period, which is assumed to be fixed in the previous analysis, may shorten as a long-run response to a rapid (positive or negative) rate of inflation. Escalator clauses would have this effect. A model where the length of the planning period is an endogenous variable is presented in our 1972 discussion paper.

V. Theoretical and Policy Implications

The Phillips Curve

The model presented in this paper suggests several labor market features that were largely ignored in earlier work on the Phillips curve. The stability of expectations is a function of the time horizon of the forecast. In most empirical work that takes account of expectations, the time horizon of the expectation is anywhere from one quarter to one year; that is, the market is viewed as being concerned with wage and price changes (or wage and price levels) that are expected to occur within the next year. The presence of a planning period lag, however, implies that the time horizon for expectations should at least be equal to the length of the planning period. In certain key manufacturing sectors of the economy the presence of union-negotiated contracts creates a planning period of two or three years in duration, which implies a relatively long time horizon. As the expectation time horizon increases in length, the expectations series for a cyclical economy such as that of the United States becomes smoother; that is, whereas the expected rate of price change anticipated by businessmen for, say, 1972 may be large (in relation to the historical mean), the expected rate of price change for the longer period of 1972 through 1975 is likely to be considerably closer to the historical mean. The smaller is the variance of the expectations series, of course, the more stable is the Phillips curve. Only significant changes in expectations or changes in expectations that do not average out over a three-year period appear in the planning period expectational series and cause a shift in the Phillips curve.[33]

Although the expectational effect increases the stability of the Phillips curve, it also introduces a long lag between current wage and price changes and past rates of inflation. Furthermore, this lag is augmented by the catch-up effect; that is, a firm which guesses incorrectly the developments over its contract period, must wait at least until the beginning of a new planning period before it can rectify the past error. The expectational and catch-up effects operate in the same direction. When the current inflation rate is, for example, above the expected rate, not only are expectations likely to increase, but also the catch-up is positive. A lack of attention to these long lags may help to explain the tendency of empirical Phillips curves to underpredict the rate of inflation between 1969 and 1972.

Social Costs and Stability

The social cost of having an administered sector is associated with the unemployment on the labor queue of the high wage sector.[34] The cost of unemployment

[33] The stability of the short-run Phillips curve is further enhanced by the inclusion of short-run frictions such as money illusion which will interact with the planning period effect in an additive fashion. Given an unanticipated inflation, the presence of money illusion on the part of workers, for example, may be indicated by an increase in the aggregate labor supply $\bar{L}$ at any given real wage rate. This enables the low wage sector to attract additional workers without the necessity of increasing relative wages (in order to draw down the queue of the high wage sector). In turn, to the extent that the queue to the high wage sector is not reduced, there is no reason for that sector to revise its wage offer. As the money illusion wears off so that $\bar{L}$ returns to its former level, the low wage sector is forced to increase ξ in order to attract additional workers. It is only at this point, with the increase in ξ and the decrease in the labor queue, that the high wage sector need adjust its wage offer.

[34] In fact, since we assume that the low wage sector clears continuously, the only cause of unemployment

is a cost to society in the form of output foregone; that is, there is a production inefficiency (arising in part from the divergence in wage rates). In addition to efficiency considerations, there is also a redistribution of income to those who are employed in the high wage sector from those who are not (whether they are in the queue or in the competitive sector).

The dynamic costs to society imposed by the administered sector turn on the question of macro-economic stabilization policy.[35] To the extent that it is understood by the policy makers, the lags associated with the planning period effect increase the stability of the system. If the dynamics of the mechanism are misunderstood, for example, if the government interprets the short-run Phillips curve as a loci of attainable long-run options, attempts to control the economy can be destabilizing.

One important potential for error concerns the identification of the source of the inflation. For example, suppose that the government increases aggregate demand from m to m' (in Figure 3) but then becomes dissatisfied with the resulting rate of inflation ξ'. It, therefore, decreases demand back to m. Unemployment increases back to U, but since administered firms are still adjusting to the past price increases, the rate of inflation at first remains above ξ. Due to the planning period lags, the government cannot lower the rate of inflation as fast as it can increase the unemployment rate.[36] The danger is that the government may erroneously decide that the economy is suffering from a cost-push inflation. Furthermore, the evidence would lend misleading support to this view. Despite the fact that unemployment is rising, the rate of wage change in the high wage (possibly unionized) sector would be greater than the wage change in the competitive sector, widening the wage structure and giving (to what is a catch-up phenomenon) the appearance of a wage or cost-push. This exercise is meant as a capsule summary of the recent *U.S.* inflation experience in the period from 1968–71, culminating in the adoption of wage-price controls in August 1971. For a further discussion of this point see the paper by Wachter (1972).

A particularly intractable problem arises when the administered sector has expectations of inflation that are greater than the rate of inflation which is desired by the government. The problem in this case is that the administered sector firms lock themselves into the higher expected rate for the length of the planning period, and the government then faces the choice of either lowering aggregate demand in the hope of reducing expectations for those firms that are beginning their planning period or validating the higher rate of inflation by increasing real balances. In the former case the anti-inflation policy results in both high unemployment and high inflation as long as it takes for expectations to be adjusted downward. If the latter policy is adopted, low unemployment can be maintained but only at the cost of spiraling inflation.

To summarize, the planning period effect permits the government to reverse any shocks that may increase the rate of inflation to an undesirable level, but if the government misinterprets the lags in the structure, it may adopt policies which are themselves destabilizing. In addition, differences between the expectations of the administered sector and the government's desired rate of inflation will be particularly difficult to deal with.

in the model is due to the queue for the administered firms. It should be stressed again that our assumption of continuous market clearing in the competitive sector is made solely to permit us to concentrate on the inflation effects of assuming a two-sector market.

[35] We will be concerned in this section principally with the instability issue itself and will not attempt to formally link this to social costs.

[36] This result may be derived from the disequilibrium dynamics of the model.

Male-Female Pay Differentials in Professional Employment

By BURTON G. MALKIEL AND JUDITH A. MALKIEL*

This study analyzes salary differentials among a sample of 272 professional employees of a single corporation. While it is dangerous to generalize from the practices of one employer, a micro-economic case study approach has several advantages. Firstly, because the employer in question hires large numbers of men and women doing the same range of jobs, a measure of the extent of sex discrimination can be obtained, holding occupation constant. It has been almost impossible to obtain such estimates in the past, since as Victor Fuchs has indicated, men are seldom employed in the occupations employing large numbers of women, and vice versa. Secondly, because the study has been confined to highly educated professional employees, the sample of men and women is relatively homogeneous with respect to career interests and attachment to the labor force. Other studies of sex discrimination have usually failed to distinguish between two very different groups of women employees: those with a long-run commitment to their occupation and those whose attachment to the labor force is temporary. Thirdly, since the employer opened its full personnel records to examination, it was possible to obtain detailed information on the previous experience and personal characteristics influencing salary differentials.[1] Such information has generally been unavailable in previous studies. Finally, because the employees in the sample have invested considerable years in higher education and in postschooling investments, an analysis of the salary differentials of this sample should provide information on the relevance of recent explanatory models of wage differentials in the human capital tradition at a level of disaggregation never used before.

After a brief review of the postschooling investment model as an explanation of salary differentials, estimates of the model as applied to men and women employees separately are presented in Section II. A somewhat expanded model, including productivity measures relevant to the employing organization, is estimated in Section III. In Section IV, the concept of discrimination is examined and estimates of discrimination against women are presented. In Section V, a "job level" variable is added to the equations and the assignment of men and women to job levels is analyzed. We conclude in Section VI that the source of any discrimination against women is in job assignments rather than in pay differentials between the sexes for the same job.

I. The Postschooling Investment Model

According to the human capital approach developed by Gary Becker and Jacob Mincer, an individual's gross an-

* Professor of economics, Princeton University and examiner, Educational Testing Service. We are grateful to Orley Ashenfelter, Alan Blinder, George Borts, Daniel Hamermesh, Jacob Mincer, Richard Quandt, and Albert Rees for many helpful comments and suggestions; Ellen Yaroshevsky for collecting the data; Elvira F. Giaimo for programming the calculations; and the National Science Foundation for financial support.

[1] We are extremely grateful to the organization, which wished to remain anonymous, for its generosity in providing us with all the personnel information available to it.

nual earnings can be related to past investments as follows:

$$W_t = W_0 + r \sum_{i=1}^{t-1} C_i \tag{1}$$

where W_t is the gross annual wage in period t; C_i is the cost of human capital investment during period i; r is the rate of return (assumed to be constant over time) to human capital investment; and W_0 is the annual wage that would be received in the absence of any human capital investments.

If formal education is the only capital investment and if the costs can be estimated as the earnings foregone during schooling, Becker and Barry Chiswick as well as Mincer have shown that equation (1) may be rewritten as

$$ln\,(W_t) = ln\,(W_0) + rS \tag{2}$$

where S represents the number of years of formal education in which the individual has specialized in human capital formation. The model can also be expanded to include investment in on-the-job training. Letting k_0 stand for the fraction of time invested in on-the-job training at the start of work experience, and assuming that such investments decline linearly over time (as by the relationship $k_j = k_0 - (k_0/T)_j$, where T stands for the years of work experience when on-the-job training ends), we may modify equation (2) as follows:

$$ln\,(W_t) = ln\,(W_0) + r_s S + r_e k_0 j - r_e \frac{k_0}{2T} j^2 \tag{3}$$

Such formulations may be found in Mincer and Thomas Johnson.

In (3), the subscripts s and e allow the rates of return for schooling and experience to differ, and j stands for the number of years of work experience. The *log* of wages is related linearly to the years of schooling (S) and in a quadratic fashion to the years of work experience (j). We call this the narrow form of the postschooling investment model.

II. Estimation of the Narrow Postschooling Investment Model

This section presents cross-sectional estimates of the narrow form of the model. The dependent variable was the employee's annual salary (or the full-time equivalent annual salary for the few part-time workers in the sample).[2] The number of years of schooling was measured as the years of education beyond high school. It was necessary in many cases to divide some of the years of graduate training into partial years of schooling and partial years of experience, as, for example, when the student held a part-time research or teaching job. The detail in the individual personnel folders made such divisions possible. Experience (outside of the present organization) was broken down into two categories: related (to the present job) work experience and unrelated experience. An example will illustrate how the division was made.

Suppose a man with two years of experience at a university or research organization was hired as a research scientist. Clearly his experience is related to the present job and undoubtedly considerable on-the-job training investments were undertaken during that period. On the other hand, if the individual came to work as a research scientist with two years' experience as a busboy after school-

[2] This wage is net of any postschooling investment in the current year. According to equations (1) to (3), however, it is the gross wage (before investment) rather than the net wage paid that is the correct dependent variable. It is likely that the discrepancy is very small, however, especially for the year 1971, since only workers already in the organization by 1968 are included in the 1971 sample. Presumably these employees have completed a considerable part of their apprenticeship period during which most of the postschooling investment takes place.

TABLE 1—ESTIMATES OF NARROW FORM OF THE POSTSCHOOLING INVESTMENT MODEL[a,b]

1969

Sample Group	Constant Term	Coefficient S	Coefficient j	Coefficient j^2	R^2	F-Value	Standard Error of Estimate
Men	8.697	+0.081 (9.93)	+0.054 (11.37)	−0.001 (8.17)	0.71	125.07 (3,155)	0.167
Women	8.504	+0.066 (6.47)	+0.059 (8.91)	−0.001 (5.45)	0.68	78.89 (3,109)	0.192

[a] Numbers in parentheses below the coefficients are t-values.
[b] S is years of schooling after high school, j is years of seniority and relevant work experience. Underneath the F-value the degrees of freedom are shown; the standard error of estimate is adjusted for degrees of freedom.

ing, the experience was coded as unrelated. Experience was coded as unrelated only if it was clearly irrelevant to the present occupation. Experience in the present organization (seniority) was simply the number of years employed. As will be explained below, related work experience outside the organization and work experience within the organization were combined into one experience variable.

The sample consists of 272 employees (159 men and 113 women) employed in fiscal year 1969 in six divisions. Their work was considered technical and/or scientific and some degree of advanced training was usually a requirement. Salaries and other personnel data were available backward in time to 1966 and forward in time through 1971. The sample numbers, however, decline in both directions (particularly going backward in time) since some of the employees at work in 1969 were not employed in 1966 and some of the 1969 employees subsequently left the organization or retired.

Cross-sectional estimates of equation (3), the narrow form of the postschooling investment model, for 1969, are presented in Table 1. As equation (3) shows, the coefficient of S may be interpreted as the rate of return to schooling. According to our estimates, men received a rate of return of 8.1 percent while women received only 6.6 percent.[3] The difference was significant at the .05 level. While the rate of return to on-the-job training (r_e) is not identified, our estimates suggest that it is at least as high as that attributable to schooling. For example, assuming that k_0, the fraction of time invested in on-the-job training at the start of work experience is one-half, one obtains an estimate of r_e in the men's equation of over 10 percent, since the coefficient of j is the product of $r_e k_0$. The number of years during which on-the-job training takes place, T, may be estimated as one-half the ratio of the coefficients of j (the experience variable) and j^2. For men the estimate is 27 years, a fairly long period, but not unreasonable in view of the technical nature of the work involved.

In Table 1, related outside work experience and experience within the organization (seniority) were combined into one experience variable. The estimated coefficients of the two types of on-the-job training were very similar when they were

[3] Equation (3) was also estimated under the assumption that the schooling variable might enter the equation as a quadratic. The estimated coefficient of the quadratic term was always negative, suggesting diminishing returns to schooling. Nevertheless, the standard error of estimate for the equation, adjusted for degrees of freedom, was never improved by the quadratic specification and therefore the linear specification was retained in this study.

TABLE 2—ESTIMATES OF NARROW FORM OF THE POSTSCHOOLING INVESTMENT MODEL USING APPROXIMATION FOR WORK EXPERIENCE[a,b]
1969

Sample Group	Constant Term	Coefficient S	Coefficient j'	Coefficient j'^2	R^2	F-Values	Standard Error of Estimate
Men	8.674	+0.091 (10.62)	+0.044 (8.83)	−0.001 (5.76)	0.66	100.63 (3,155)	0.180
Women	8.573	+0.078 (6.00)	+0.037 (5.32)	−0.001 (4.07)	0.47	32.07 (3,109)	0.248

[a] Numbers in parentheses below the coefficients are t-values.
[b] $j' = Age - (18+S)$. Other terms are defined in Table 1.

allowed to enter the equation separately.[4] Nonrelated work experience was dropped from the equation since estimates of the coefficient of such experience were never significant.[5] As will be indicated later, we also were able to reject the hypothesis that the salaries of men and women were generated by the same pay structure.

Most previous empirical studies have not had available precise information on work experience. Such experience has usually been estimated as the number of years since the completion of schooling, i.e., $j' = Age - (18+S)$. The results of using such an estimate of work experience is presented in Table 2.

Comparison of the two tables indicates that the crude approximation of experience seems to work well for the sample of men. The R^2 and the coefficient estimates are quite similar in the two tables. The differences are much greater for the women's equations and the R^2 falls sharply. The approximation worked less well for women since many women in the sample spent several years after formal schooling out of the labor force or in nonrelated work activities.

We also attempted to add age variables to equation (3), which included only schooling and experience. Perhaps there is a maturation process with age that affects salaries apart from the postschooling investments associated with work experience. To answer this question we estimated equation (4) but could not accept the hypothesis that the coefficients of the added age variables were jointly significantly different from zero.[6]

[4] For example, during 1969, the following coefficients (and t-values) were obtained when seniority and related work experience were allowed to enter equation (3) separately, as first and second degree terms.

	Men	Women
Related Work Experience	+ 0.041 (6.00)	+ 0.044 (4.46)
Related Work Experience²	− 0.001 (3.85)	− 0.001 (2.09)
Seniority	+ 0.049 (4.64)	+ 0.046 (3.47)
Seniority²	− 0.001 (2.92)	− 0.001 (1.65)

It should be also noted that the standard error of estimate (adjusted for degrees of freedom) for the equation was higher when seniority and related experience entered the equations separately.

[5] For example, for the year 1969 when the number of years of nonrelated work experience was added (as a separate independent variable) to equation (3), the estimated coefficients for men and women were +0.003 with standard errors of (0.004).

[6] The hypothesis was tested by calculating the ratio

$$F = \frac{[R^2(4) - R^2(3)]/2}{[1 - R^2(4)]/(n-6)}$$

where $R^2(4)$ and $R^2(3)$ are the coefficients of determination obtained from the estimates of equations (4) and (3), respectively, and n is the number of observations.

$$(4) \quad ln\,(W_t) = ln\,(W_0) + r_s S + r_e k_0 j - r_e \frac{k_0}{2T} j^2 + \alpha_1 Age + \alpha_2 Age^2 + \mu$$

This result held in both the men's equation and the women's equation, where the collinearity between the age and experience variables was less severe.

III. An Expanded Wage Model

Thus far the wage for an individual employee is assumed to be fully explained on the basis of schooling and postschooling investments. Perhaps the major missing elements in our explanation of salary differentials concern the various personal and productivity characteristics that influence the employment situation. It is, of course, very difficult to measure an individual's productivity independently of the salary decision. Nevertheless, proxy variables may be employed to estimate the individual's productivity and opportunities for alternative employment.

Given the scientific and technical nature of the output of the particular divisions of the corporation chosen for study, a variable measuring the extent of the individual's publications may serve as a useful proxy for productivity. An individual's value to the organization, and certainly his or her ability to generate outside job offers, is related to the employee's professional reputation. Individuals obtain outside reputations in scientific fields primarily through published work. Consequently we added a variable indicating the extent to which the individual had made important scientific contributions through his writing.

A cardinal measure of the individual's publications is not necessarily indicative of the employee's professional reputation or worth to the corporation. Consequently, we used a dummy variable, which took on the value "1" if the individual had made significant contributions and "0" otherwise. Several methods of coding the dummy variable were tried, based on the number of publications. All were successful, but the most satisfactory method combined a quantity and quality measure. The variable took on the value "1" if the individual had fifteen or more publications or, where publications were fewer than fifteen, a group of professionals in the individual's field judged that the publications were outstanding and so well known in the literature that he or she had achieved a distinguished outside reputation.

We also utilized a dummy variable indicating whether or not the individual had received the Ph.D. degree. Consider two individuals who spend four years each in graduate school. The first manages to obtain only a master's degree during the period while the second completes a dissertation and receives a doctorate. We suggest that the second individual is likely to be a more productive worker and will command a higher salary.

Another variable was added to indicate the individual's marital status. The variable was coded "1" if the individual was married and "0" if the individual was single. It has been argued by William Bowen and T. Aldrich Finegan that employers may regard an individual's marital status as a proxy for personal traits relating to success in the work environment. Family and marital responsibilities may make married men more stable than single men and, therefore, married men get the better-paying jobs. Also the employer may rationalize the payment of higher wages to married men because their financial requirements are greater. On the other hand, employers may expect married women to have higher absence and turnover rates, that is, they are "less stable" employees. For example, it is generally

presumed by employers that a working wife will quit her job when the husband's job changes so as to require the family to move.[7]

The actual number of years of schooling and on-the-job training may not capture adequately the quality of the investment made. The area in which an individual has undertaken undergraduate and graduate study may have an important bearing on salary prospects. For example, individuals with training in mathematics, statistics, and operations research would find many high paying opportunities available with universities, government agencies, or corporations. Other individuals trained in English literature might find only relatively low paying jobs available at universities or, perhaps, with publishing firms or similar employers. Thus, people with "critical" skills have a much higher opportunity cost and need larger salaries to be attracted to and retained by the organization.

In coding the employees with respect to the critical nature of their areas of study, we used a study, prepared for the American Economic Association, of median salaries for Ph.D.'s in alternative fields. The highest of these were regarded as critical areas of study. For the purposes of the present study, the fields of mathematics, statistics, and several of the physical sciences were coded as critical. A dummy variable, D_c, was employed which took on the value unity if the individual's area of study was a critical one, and zero otherwise.

Finally, each individual's absence rate, was added as an independent variable. Absence might have two effects on salaries. First, annual salaries for workers with a history of absence might be lowered to reflect the expectation that such employees would work fewer days per year. Second, absence may be related to looser work habits and may thus serve as a proxy for worker productivity. Workers who are frequently absent may be less productive even when they are on the job. The variable used in the regression was defined as simply the number of days absent per year other than vacation time, averaged over the preceding four years (or over the number of years employed if less than four).

As an expanded wage model, we therefore add to equation (3), the personal and productivity factors noted above. The broadened equation was

$$(5)\quad ln\,(W_t) = a_0 + a_1S + a_2j + a_3j^2 + a_4D_{PHD} + a_5D_{PUB} + a_6D_M + a_7D_c + a_8A + \eta$$

where D_{PHD}, D_{PUB}, D_M, and D_c stand for the Ph.D., publications, marital status, and critical area-of-study dummies, respectively, and A stands for the absence rate. Estimates of equation (5) for the years 1966, 1969, 1970, and 1971 are shown in Table 3.

Table 3 indicates that the additional "productivity" proxy variables do improve our ability to predict salary levels for men and women in the organization.[8] In most cases more than three-fourths of the variance in men's salary levels is explained by the regressions, while over 80 percent of the variance in women's salaries is explained. The coefficient of the dummy variable associated with publica-

[7] In fact, as will be shown below, the absence rate was much higher for women than for men, although marital status itself was not related to absence. A previous study of the organization was unable to isolate differences in turnover among men and women. It is for this reason we suggested earlier that the sample was relatively homogeneous with respect to the employee's attachment to the job.

[8] Utilizing an F-test similar to that described in fn. 6, we verified that the addition of the productivity variables was highly significant in all years. Nevertheless, the increase in R^2 over the narrow form of the model is only moderate, indicating the robustness of the cruder model.

TABLE 3—ESTIMATES OF EQUATION (5)[a]

Sample Group	Constant Term	Coefficient of S	j	j^2	D_{PHD}	D_{PUB}	D_M	D_c	A	R^2	F-Value	Standard Error of Estimate
Men 1971	9.008	+0.036	+0.044	−0.001	+0.118	+0.147	+0.145	+0.066	−0.005	0.68	31.83	0.161
		(2.77)	(7.28)	(5.18)	(2.67)	(2.91)	(2.88)	(1.99)	(1.09)		(8,120)	
Women 1971	8.719	+0.044	+0.061	−0.001	+0.047	+0.355	−0.013	+0.216	−0.015	0.83	49.83	0.155
		(3.88)	(7.90)	(4.65)	(0.81)	(3.54)	(0.39)	(5.36)	(4.62)		(8,84)	
Men 1970	8.790	+0.042	+0.051	−0.001	+0.121	+0.112	+0.183	+0.078	−0.001	0.76	53.88	0.156
		(3.41)	(10.09)	(7.10)	(2.95)	(2.40)	(4.18)	(2.50)	(1.24)		(8,133)

[a] The numbers underneath the coefficients are the related t-statistics.
Note: S, j, are defined in Table 1; D_{PHD}=Ph.D.; D_{PUB}=publications; D_M=marital status; D_c=critical area-of-study; and A stands for the absence rate.

tions always had the correct sign and usually was highly significant. Similarly, the receipt of the Ph.D. and study in a critical area were typically associated with higher salary levels. Of course, the coefficients of S and j shrink and lose their former interpretation because the Ph.D. and publications variables represent unmeasured aspects of investment in S and j, respectively, and are correlated with them. Finally, the marital status dummies took on their expected signs, although the coefficients for women were never significant. The coefficient of the absence rate was typically negative and especially significant for women.[9]

[9] It should be noted that we were unsuccessful in finding a relationship between several other variables and the structure of salaries. We tried, for example, to measure the quality of education by obtaining the quality rating of the institution at which the education was received, and also by looking at whether or not the individual received academic honors. We could find no relationship between either variable and the structure of salaries. Our procedure was to add explanatory variables to the salary structure equations until further additions failed to reduce the standard error of the estimate adjusted for degrees of freedom.

As in the narrow form of the postschooling investment model, we were able to reject the hypothesis that the structural salary relationships estimated for men and women were the same. The null hypothesis that the two equations had the same slopes and constant terms was rejected at the 1 percent level in each year on the basis of the standard Chow test. While many of the slope coefficients were not significantly different, differences in the overall structure were caused by significant differences in the constant terms and in the coefficients of most of the dummy variables. As noted above, the similarity of the schooling and experience coefficients (compared with the narrow model) should not be taken to indicate that the rates of return for men and women are the same.

IV. Adjusted Salary Differentials or Discrimination Measures

Gross differences in average salaries between men and women (i.e., $\overline{W}_m - \overline{W}_w$) do not indicate the presence of discrimina-

tion. If women, on average, have less education and job experience than men, we should anticipate that their average salaries would be lower. Discrimination can be said to exist only if women with the same characteristics as men tend to receive lower salaries.

The basic technique involved in estimating salary differentials adjusted for differences in personal and productivity characteristics is to compare the average wages that would be received by the two groups if they were paid according to the same salary structure. Two different types of assumptions are possible. We could assume that in the absence of discrimination, both men and women would face the salary structure applicable for men, or that both sexes would face the salary structure applicable for women.

We define $\tilde{W}_w$ as the average salary women would receive if they were paid by the salary structure applicable for men. We may estimate $\tilde{W}_w$ by

$$(6) \qquad \tilde{W}_w = f_m(\bar{S}_w, \bar{j}_w, \bar{\phi}_w)$$

where f_m stands for the pay structure relationship estimated for men. It will be noted that equation (6) evaluates the function at the mean values of the schooling, experience, and ϕ_w, the vector of "productivity" variables applicable to the women in the sample. The gross difference in average salaries between men and women $(\overline{W}_m - \overline{W}_w)$ may be decomposed into two components: 1) the difference in salaries due to different characteristics, which may be estimated as $\overline{W}_m - \tilde{W}_w$, and 2) the differential remaining after adjustment for differing characteristics, i.e., $\tilde{W}_w - \overline{W}_w$, which may be interpreted as a measure of sex discrimination.[10]

Alternatively, we define $\tilde{W}_m$ as the average salary men would receive if they were paid according to the women's pay structure. Then $\tilde{W}_m$ may be estimated by

$$(7) \qquad \tilde{W}_m = f_w(\bar{S}_m, \bar{j}_m, \bar{\phi}_m)$$

where f_w, the pay structure function estimated for women, is evaluated at the mean values of the characteristics variables. As before, the gross difference in wages can be decomposed into that component due to differing characteristics, $\tilde{W}_m - \overline{W}_w$, and the adjusted difference remaining, $\overline{W}_m - \tilde{W}_m$.

Table 4 presents the average salaries for men and women for the period studied and a decomposition of the gross differentials. The top part of the table is based on the regressions estimating the narrow form of the postschooling investment model (equation (3)), the bottom part is based on the expanded model of equation (5). Women's salaries have consistently averaged only about two-thirds of the salaries for men. The gross difference in salaries, \$7,000 in 1971, should not be attributed to discrimination, however. Even if women were paid according to the same salary relationship existing for men, they would still earn only about 80 percent of the salary of men.

Large salary differentials would remain even if the same pay structure prevailed for men and women. The reasons are indicated in Table 5, which shows by sex the mean values for the independent variables of the wage-structure equation. The women in the sample are less endowed with the characteristics preferred by the organization. Women had less education, related work experience, and seniority than the men and more unrelated experience.[11] In addition, a smaller

[10] This approach is similar to the one employed by Ronald Oaxaca.

[11] Of course, culture, tradition, and even overt discrimination may explain why women do not have the same training and experience as men. Women may have been discouraged from graduate training and from particular fields of study such as mathematics and physics. They may, by choice, have devoted a number of years of their working lives to childbearing and household activities.

percentage of women studied in critical areas, gained the Ph.D., or had published significantly. Finally, women tended to have considerably higher absence rates than men. As the bottom rows of Table 4 show, the major part of the gross difference in wages can be attributed to the differential training and other job characteristics women bring to the employment situation. Estimates of discrimination or "adjusted salary differentials" tended to be somewhat higher when salary structures are based on the narrow postschooling investment model. This is because women were less endowed than men with qualities we have suggested may proxy for worker productivity.

It may be argued that our analysis of adjusted salary differentials is biased because some of the independent variables measure different things in men and women. The primary example is marriage, which employers may tend to associate with maturity and stability for men and divided responsibilities for women. It may be unreasonable to say that in the absence of discrimination married women would earn more than single ones—but this is

TABLE 5—AVERAGES OF VARIABLES

Means	1971 Men	1971 Women	1970 Men	1970 Women	1969 Men	1969 Women	1966 Men	1966 Women

Percent of sample married	0.91	0.62	0.89	0.62	0.89	0.61	0.92	0.61

precisely what is assumed when the equation for men is used together with the means of the women's characteristics variables.

To judge the effects of such "bias" we ran the same experiment omitting the marital status variable. The resulting estimates of discrimination against women were actually a bit larger than those presented in Table 4 for the expanded model. The inclusion of marital status reduces estimated discrimination. Since far fewer women were married, including marriage as a desirable characteristic tended to make the "justifiable" difference in average men's and women's salaries larger.

Table 4 indicates that, in percentage terms, the adjusted salary differential in the organization has decreased since 1966 although it rose in 1970, compared with the preceding two years. Our estimates of discrimination, while substantial, are somewhat lower than those of other investigators, who have studied mainly the less skilled occupations. Fuchs finds that even after adjusting for education, women's salaries tend to be about 60 percent of those for men, and indicates that such a percentage can be found in the Bible, the code of Hammurabi, and in data on the price of slaves in the antebellum South. Oaxaca, using a human capital approach and survey data collected in February 1967, found somewhat greater adjusted salary differentials than those reported here for 1966. These comparisons suggest that estimates of discrimination may be less for a relatively homogeneous sample such as utilized here.

V. Analysis of Regression Results Using a "Job Level" Variable

Starting in 1971, the corporation provided a thirteen-point ranking of job levels, designed to indicate the individual's level of responsibility. Since job levels had salary ranges associated with them, it was expected that the salary and level variables would be highly correlated. Indeed, the simple correlation between the two variables was about 0.8. Consequently, when level was added as an independent variable to equation (5), many of the t-values associated with the independent variables became insignificant. Nevertheless, it was possible to include some of the independent variables from (5) together with level to explain the structure of salaries in 1971. The equation estimated was

$$\text{(8)} \quad ln\,(W_t) = a_0 + a_1S + a_2j + a_3j^2 + a_4D_{PUB} + a_5D_c + a_6A + a_7L + \epsilon$$

where L stands for the workers job level. The estimates of equation (8) are shown in the top half of Table 6. As expected, the coefficients of determination improve considerably compared with those reported previously.

The bottom half of Table 6 presents an analysis of the related salary differentials, as was shown in Table 4. Essentially, all the adjusted salary difference, or "discrimination," seems to disappear. The gross salary differentials can now fully be explained by differences in worker characteristics, including job level. What has happened is that women, on average, have considerably lower job levels than the men. Given the job levels to which women are assigned, they tend to make about the same salaries as men.

The question immediately arises, however, why women are assigned to much lower job levels than men. Can this be explained by their lower levels of training and education, or does the organization discriminate in assigning men and women to particular job levels? This can be analyzed by the same techniques employed above. We can try to explain assignment to job levels on the basis of the same types of employee characteristics

TABLE 6—ESTIMATES OF EQUATION (8) WITH JOB-LEVEL VARIABLE

1971

Sample Group	Constant Term	Coefficient of S	j	j^2	D_{PUB}	D_c	A	L	R^2	F-Value	Standard Error of Estimate
Men	8.582	+0.017 (3.19)	+0.016 (4.50)	−0.0003 (3.54)	+0.127 (4.73)	+0.038 (2.16)	−0.005 (1.90)	+0.109 (18.34)	0.91	166.66 (7,121)	0.087
Women	8.563	+0.019 (2.78)	+0.028 (4.80)	−0.0005 (3.13)	+0.281 (4.39)	+0.147 (5.46)	−0.006 (2.73)	+0.081 (10.83)	0.93	155.78 (6,85)	0.101

Analysis of Related Salary Differentials

	Men A		Women B	B/A in Percent
Average Salary	\$20,273		\$13,273	65.47
Salary if men and women were paid according to relationship for men	20,273		13,419	66.19
Salary if men and women were paid according to relationship for women	17,385		13,273	76.35
Gross Difference $\overline{W}_m - \overline{W}_w$		7,000		100.00
Difference due to different characteristics $\overline{W}_m - \tilde{W}_w$		6,854		97.91
Adjusted difference remaining $\tilde{W}_w - \overline{W}_w$		146		2.09

Note: the term L stands for workers' job level; S, j are defined in Table 1; D_{PUB}, D_c, A are defined in Table 3.

previously used to explain salary differentials. The specific equation employed was

$$(9)\quad L = \alpha_0 + \alpha_1 S + \alpha_2 j + \alpha_3 j^2 + \alpha_4 D_{PHD} + \alpha_5 A + \alpha_6 D_{PROD} + \alpha_7 D_M + \alpha_8 D_c + v$$

where D_{PROD} was a dummy variable, which took on the value unity if an individual employee worked in the "production" division, where job level assignments tended to be relatively low. The results of this exercise are shown in the top half of Table 7. Education, experience, and other characteristics can be used to make reasonably good predictions of an employee's job level.[12]

The bottom half of Table 7 presents an analysis of the differences in levels. The analysis is the same as was carried out for salary differences. On average, the level for men employees was 2.8 level steps higher than for women. Almost one-half of this gross difference can be attributed to the different characteristics of the men and women in the sample. Women can be expected to be 1.31 level steps lower than men because of their lower level of education, experience, etc. The remaining half of the difference remains unexplained and may be attributed either to discrimination against women or to other productivity characteristics, which differ by sex and which we were unable to measure.

VI. Conclusion

This study has attempted to answer two questions. 1) Can the structure of salaries in an individual organization be explained

[12] Equation (9) was reestimated under an assumption that the relationship between absence rate and level was a simultaneous one. We assumed that the absence rate affects level, but that the level assignment also affects the absence rate, particularly for women. We hypothesized that women assigned to low job levels (inappropriate to their training) might be bored with their assignments and, therefore, be absent more. Thus, the absence rate, A, was hypothesized to depend upon age and level, L, in the following fashion:

$$A = \beta_0 + \beta_1 Age + \beta_2 Age^2 - \beta_3 L + \delta$$

When equation (9) was reestimated with a two-stage least squares technique, the coefficient estimates were essentially the same as those reported above. Moreover, the estimated coefficient, β_3, of the absence rate equation above was not significantly different from zero. We did find, however, that the age was important in explaining absence. The estimated coefficient β_2 was positive indicating that the older employees were more likely to be absent from work. The age variables explain only a small part of the variance in absence rates, however. Absence was found to be unrelated to such plausible explanatory variables as marital status and presence of children under six years of age for women.

Table 7—Estimates of Equation (9) Predicting Job Levels

1971

Sample Group	Constant Term	Coefficient of S	j	j^2	D_{PHD}	A	D_{PROD}	D_M	D_c	R^2	F-Value	Standard Error of Estimate
Men	4.025	+0.259 (2.52)	+0.255 (5.34)	−0.004 (3.68)	+0.668 (1.88)	−0.010 (2.69)	−0.533 (1.79)	+0.924 (2.35)	+0.233 (0.89)	0.53	17.06 (8,120)	1.271

Analysis of Level Differentials

	Men A		Women B	B/A in Percent
Average Level	9.38		6.58	70.15
Level if men and women were assigned job levels according to relationship for men	9.38		8.07	86.03
Level if men and women were assigned job levels according to relationship for women	8.24		6.58	79.85
Gross Difference in Levels		2.80		100.00
Difference due to differing characteristics of men and women in sample (assuming men and women were assigned levels according to the relationship for men)		1.31		46.79
Difference remaining		1.49		53.21

Note: D_{PROD} stands for workers in production; S, j are defined in Table 1; D_{PHD}, D_M, D_c, A are defined in Table 3.

by such variables as education, experience, and productivity proxies? 2) Is there discrimination against women; that is, do women with job characteristics equal to those of men fail to get the same pay?

We have been quite successful in answering to the first question. Experience, education, and productivity variables are able to explain over three-quarters of the variance in salaries for both men and women over several years. The answer to the second question depends upon how narrowly or broadly one perceives the problem. If the question is posed, "Do men and women in equal job levels, with the same characteristics, get equal pay?" the answer is "Yes." If, on the other hand, the question is posed, "Do men and women, with equal characteristics, get equal pay?" the answer is "No." The reason for the difference in answers is that women with the same training, experience, etc. as men tend to be assigned to lower job levels.

It is, of course, possible that such a pattern of job assignment does not reflect discrimination. Other explanations may be preferences of men and women for more or less responsibility or biases resulting from our culture and tradition which may affect productivity characteristics of men and women other than those that we were able to measure and include in the study. It seems highly improbable, however, that such missing variables would fully account for the pattern of job level assignments or for the adjusted salary differentials we have isolated. We suggest that it is difficult for a discriminating organization to give male and female employees the same titles and pay them different amounts. It is far easier to assign women to lower job levels and then set up a pay structure by level that is the same for both sexes. Thus, our analysis of salary differentials including job levels should not be interpreted as indicating an absence of discrimination. The assignments to job levels can most plausibly be interpreted as the mechanism by which the discrimination takes place.

Nontraded Goods, Factor Market Distortions, and the Gains from Trade

By RAVEENDRA N. BATRA*

The purpose of this paper is to explore one by one the implications of a change in the rate of tariff and the terms of trade for community welfare in an economy where some goods are traded and some nontraded and where factor markets are distorted by the presence of invariant interindustry wage differentials. Despite the claim to the contrary by Murray Kemp,[1] we find that an increase in the rate of tariff may actually lead to a rise in welfare even when distortions are absent. Another major result of this note is that, unlike the results derived by Jagdish Bhagwati and V. K. Ramaswami, free trade alone may turn out to be the second best policy in the presence of distortions, provided the higher wage rate is paid by the import-competing industry or the wage rates differ among all industries. Furthermore, unlike the traditional two-good models, factor proportions may play a significant role in determining the fate of several standard theorems concerning the gains from trade.

I. Assumptions and the Model

Unless otherwise specified, we assume that there is a small country which produces three goods, X_1, X_2, and X_3, with the help of given supplies of two factors of production, capital (K) and labor (L). In its trade relations with the rest of the world it takes the international price ratio as given, exports X_2 and imports X_1. The third good, X_3, is not traded. There is perfect competition in product markets, and production functions are homogeneous of the first degree. Factor markets are characterized by a) perfect internal mobility of factors, and perfect factor-price flexibility, and b) the reward of capital is the same in all three sectors, but the wage rate differs among all three industries *in spite of the factor mobility*. There is full employment of factors, which is ensured by the presence of factor-price flexibility. Foreign trade is stable and inferior goods are absent. In addition all goods are gross substitutes.

Let U denote the total utility which a community derives from the consumption of the three goods, with their demand denoted by D_i ($i=1, 2, 3$). Then

(1) $$U = U(D_1, D_2, D_3)$$

(2) $$D_1 = X_1 + E_1$$

(3) $$D_2 = X_2 - E_2$$

(4) $$D_3 = X_3$$

where E_1 equals the import of the first commodity and E_2 equals the export of the second commodity. The balance of trade equilibrium requires that

(5) $$P_1E_1 = P_2E_2$$

where P_j is the given foreign price of the jth traded good ($j=1, 2$). The three linearly homogeneous production functions are given by

(6) $$Xi = F_i(K_i, L_i) = L_if_i(k_i) \quad (i = 1, 2, 3)$$

where K_i and L_i are the capital and labor inputs and $k_i=K_i/L_i$ is the capital-labor ratio in the ith commodity. Let F_{Ki} and F_{Li} be the marginal productivity of capital and labor, respectively, in the ith commodity. Then $F_{Ki}=f_i'$ and $F_{Li}=f_i-k_if_i'$. The price of each factor of production equals the value of its marginal product. With the reward of capital assumed to be the same in all industries,

(7) $$r = P_1f_1' = P_2f_2' = P_3f_3'$$

* Professor of economics, Southern Methodist University. I wish to express my gratitude to V. S. Rao for useful discussions and to the editor and an unknown referee for suggesting several refinements. This research was supported by a grant from Canada Council.

[1] See Kemp, ch. 12, note 13, p. 267.

where P_3 is the price of the nontraded good. However, in the presence of the wage differentials in all industries

$$(8)\qquad \frac{P_1(f_1 - k_1 f_1')}{\alpha_1} = \frac{P_2(f_2 - k_2 f_2')}{\alpha_2} = \frac{P_3(f_3 - k_3 f_3')}{\alpha_3}$$

where $\alpha_i \geq 1$ $(i=1, 2, 3)$ is a constant. Under full employment,

$$(9)\qquad L_1 + L_2 + L_3 = L$$

and

$$(10)\qquad K_1+K_2+K_3=L_1k_1+L_2k_2+L_3k_3=K$$

This completes the specification of our model which allows for the presence of the factor-price differential as well as a nontraded good.

The Relationships Among X_1, X_2, and X_3

For a small country P_1, P_2, and hence P_3 are given, so that k_i is constant.[2] Differentiating X_1 and X_2 from (6) with respect to X_3, we obtain

$$\frac{dX_i}{dX_3} = f_i \frac{dL_i}{dX_3} \qquad (i = 1, 2)$$

Substituting this in the differentiation of the full employment equations (9) and (10) then yields

$$(11)\qquad \frac{dX_1}{dX_3} = \frac{f_1(k_3 - k_2)}{f_3(k_2 - k_1)}$$

$$(12)\qquad \frac{dX_2}{dX_3} = \frac{f_2(k_1 - k_3)}{f_3(k_2 - k_1)}$$

Equations (11) and (12) reveal the importance of factor proportions in the three industries in the determination of the relationships among X_1, X_2, and X_3. For expository purposes, we also need the relationship between the production-possibility surface and the price plane in the presence of the inter-industry wage differentials.

[2] Ryutaro Komiya has shown that if P_1 and P_2 are constant, P_3 also remains constant.

Totally differentiating X_1 and X_2 in (6) and dividing through by dX_2, we obtain

$$(13)\qquad \frac{dX_1}{dX_2} = \frac{F_{K1}dK_1 + F_{L1}dL_1}{F_{K2}dK_2 + F_{L2}dL_2}$$

From (9) and (10),

$$dL_1 + dL_2 + dL_3 = dK_1 + dK_2 + dK_3 = 0$$

Using these relations and (7) and (8), (13) can be written as

$$(14^*)\qquad \frac{dX_1}{dX_2} = -\frac{P_2}{P_1} \cdot \left[\frac{F_{K2}(dK_2+dK_3)+(\alpha_1/\alpha_2)F_{L2}(dL_2+dL_3)}{F_{K2}dK_2+F_{L2}dL_2}\right]$$

or

$$(14)\qquad \frac{dX_1}{dX_2} = -\frac{P_2}{P_1} \cdot \left[\beta + \frac{F_{K2}dK_3 + (\alpha_1/\alpha_2)F_{L2}dL_3}{F_{K2}dK_2 + F_{L2}dL_2}\right]$$

where

$$\beta = \frac{F_{K2}dK_2 + (\alpha_1/\alpha_2)F_{L2}dL_2}{F_{K2}dK_2 + F_{L2}dL_2} \gtreqless 1$$

according as $(\alpha_1/\alpha_2) \gtreqless 1$. This follows from the fact that dK_i and dL_i and hence the numerator and the denominator of β have the same signs.[3] In the same manner, we can write that

$$\frac{dX_3}{dX_2} = \frac{P_2}{P_3}\left[\frac{F_{K2}dK_3 + (\alpha_3/\alpha_2)F_{L2}dL_3}{F_{K2}dK_2 + F_{L2}dL_2}\right] = \frac{P_2}{P_3}\left[\frac{F_{K2}dK_3 + (\alpha_1/\alpha_2)F_{L2}dL_3}{(F_{K2}dK_2 + F_{L2}dL_2)\lambda}\right]$$

where

$$\frac{1}{\lambda} = \frac{F_{K2}dK_3 + (\alpha_3/\alpha_2)F_{L2}dL_3}{F_{K2}dK_3 + (\alpha_1/\alpha_2)F_{L2}dL_3} \gtreqless 1$$

[3] This can be readily seen by comparing the production points along the contract curve in the Edgeworth-Bowley production box diagram in the two-good, two-factor case and in the Melvin type box diagram in the three-good, two-factor case. The reader will find that the rise in the output of the ith good is accompanied by the rise in both K_i and L_i, and conversely.

if $(\alpha_3/\alpha_2)\gtreqless(\alpha_1/\alpha_2)$, or $\lambda 1, \gtreqless 1$ according as $(\alpha_1/\alpha_3)\gtreqless 1$. It may now be seen that the second term within the brackets of (14) equals $(\lambda P_3/P_2)(dX_3/dX_2)$. Hence

$$(15^*) \quad \frac{dX_1}{dX_2} = -\frac{P_2}{P_1}\left[\beta + \frac{\lambda P_3}{P_2}\cdot\frac{dX_3}{dX_2}\right]$$

or

$$(15) \quad P_1dX_1 + \beta P_2dX_2 + \lambda P_3dX_3 = 0$$

Equation (15) shows that the price plane is not tangential to the production-possibility surface. In the absence of the wage differential, however, $\alpha_i=\beta=\lambda=1$, so that (15) reduces to $P_1dX_1+P_2dX_2+P_3dX_3=0$.

II. Welfare and the Change in the Terms of Trade

In this section we examine the Batra-Pattanaik theorem (derived in the absence of the nontraded goods) that an improvement in the terms of trade may result in a loss of welfare, and vice versa, if the wage differential is paid by the importable good. In our model, X_2 is the exportable good and X_1 the importable good. Therefore an exogenous improvement (deterioration) in the terms of trade can result from a rise (fall) in P_2 alone, or a fall (rise) in P_1 alone. Let us consider the implications for welfare of a slight change in P_2 only, keeping P_1 constant. Differentiating the social utility function given by (1) totally with respect to P_2, and dividing through by U_1, we get

$$(16) \quad \frac{1}{U_1}\,\frac{dU}{dP_2} = \frac{dD_1}{dP_2} + \frac{U_2}{U_1}\cdot\frac{dD_2}{dP_2} + \frac{U_3}{U_1}\cdot\frac{dD_3}{dP_2}$$
$$= \frac{dD_1}{dP_2} + \frac{P_2}{P_1}\cdot\frac{dD_2}{dP_2} + \frac{P_3}{P_1}\cdot\frac{dD_3}{dP_2}$$

where $U_i=\partial U/\partial D_i>0$, $(U_2/U_1)=(P_2/P_1)$ and $(U_3/U_1)=(P_3/P_1)$. Differentiating (2)–(5) with respect to P_2, dividing through (15) by P_1dP_2, substituting dX_1/dP_2 in (16) and remembering that $(dD_3/dP_2)=(dX_3/dP_2)$, we obtain

$$(17) \quad \frac{1}{U_1}\,\frac{dU}{dP_2} = \frac{E_2}{P_1} + \frac{P_2}{P_1}\cdot\frac{dX_2}{dP_2}(1-\beta) + \frac{P_3}{P_1}\,\frac{dD_3}{dP_2}(1-\lambda)$$

This last equation furnishes the long sought after relationship between the terms of trade and welfare measured in terms of the first commodity. The following results may now be derived.

1. Suppose the wage differential exists, but the nontraded good does not. Following Batra and Pattanaik, it is assumed that $dX_2/dP_2>0$ in spite of the wage differential. Then if $\beta>1$, it can be easily seen that an improvement (deterioration) in the terms of trade may lead to a loss (rise) in welfare. Now $\beta>1$ implies that $\alpha_1>\alpha_2$, which from (8) means that the differential (or the higher wage) is paid by importable goods. This is a simple proof of the Batra-Pattanaik result and is obtained as a special case of the general equation (17).

2. Suppose that the nontraded good exists. We have already established that $\beta\gtreqless 1$, if $(\alpha_1/\alpha_2)\gtreqless 1$ and that $\lambda\gtreqless 1$, if $(\alpha_1/\alpha_3)\gtreqless 1$. Let us first consider the case where the differential is paid by the nontraded good. Here $1=\alpha_1=\alpha_2<\alpha_3$, so that $\beta=1$ and $\lambda<1$. Under our assumption that all commodities are gross substitutes, $(dD_3/dP_2)>0$. Hence from (17), we can see that $(1/U_1)(dU/dP_2)>0$. *Thus we conclude that if the wage differential is paid by the nontraded good, and if the commodities are gross substitutes, then an improvement (deterioration) in the terms of trade results in an improvement (deterioration) in welfare.* This is a straightforward generalization of the theorem by Anne Krueger and Hugo Sonnenschein.[4] What is more interest-

[4] That the wage differential is paid by the nontraded good sector is not a mere theoretical possibility. There is a logical explanation for why the contrary may be untrue. Since the traded goods face strong competition from foreign producers which the nontraded goods do not, the employers in the nontraded goods may be more prone to accept union demands for higher wages than the employers in the trade goods. Recent restrictions introduced in the United States by President Nixon on the spiralling wage gains by unions in the construction industry, which is a very good example of a nontraded good industry, would lend credence to our

ing is that the change in welfare is even greater than what would result in the absence of the wage differential.

3. Of greater interest is the case where the differential is paid by the import competing industry so that $1=\alpha_2=\alpha_3<\alpha_1$. Here the results turn out to depend crucially on factor-proportions in all three industries. For by using (12), (17) can be written as

$$(18)\quad \frac{1}{U_1}\cdot\frac{dU}{dP_2}=\frac{E_2}{P_1}+\frac{P_3(1-\lambda)}{P_1}\frac{dD_3}{dP_2}\cdot\left[1+\frac{P_2(1-\beta)}{P_3(1-\lambda)}\cdot\frac{f_2(k_1-k_3)}{f_3(k_2-k_1)}\right]$$

With the wage differential paid by the importable good only, λ and β are both greater than unity, so that $(1-\lambda)<0$ and $(1-\beta)/(1-\lambda)>0$. The effect of a change in P_2 on welfare then depends on the sign of the terms within the brackets, and hence on the factor proportions in the three industries. A sufficient condition for the terms of trade to have a positive relationship with social welfare is that the square bracketed term is zero or negative, that is

$$(19)\qquad \frac{P_3(1-\lambda)}{P_2(1-\beta)}\leq\frac{f_2(k_3-k_1)}{f_3(k_2-k_1)}$$

Since the left-hand side of (19) is positive, a necessary condition for (19) to be satisfied is that its right-hand side be positive, which in turn requires that either $k_1\gtrless k_3\gtrless k_2$ or $k_1\gtrless k_2\gtrless k_3$. However, condition (19) is violated if k_1 lies between k_2 and k_3, so that with $\lambda>1$, an improvement in the terms of trade may then lead to a loss of welfare, and conversely. This is a variant of the Batra-Pattanaik theorem and it highlights the role of factor proportions of the three industries in determining the implications of a change in the terms of trade for welfare, when the differential is paid by the importable good and all goods are gross substitutes.

One may also wish to analyze the effects of the wage differentials prevailing in all the industries. In this case, the results derived above may be reinforced or attenuated. It is of some interest to note here that the effects of the wage differentials among all three industries may cancel out each other and leave the standard theorem unscathed. The necessary condition for this "cancelling effect" is again given by condition (19) with equality.

III. Higher Versus Lower Tariffs

This section is concerned with the implications of a rise in the rate of tariff on welfare. Assume that a small tariff already exists on the imports of the first commodity, so that $P_1^*=P_1(1+t)$, where P_1^* is the domestic, tariff-inclusive price for the importable commodity and t is the rate of nonprohibitive tariff. With P_1 constant, $dP_1^*/dt=P_1>0$. Differentiating (1)–(5) with respect to t and remembering that here $U_2/U_1=P_2/P_1^*$ and $U_3/U_1=P_3/P_1^*$, we obtain

$$(20)\quad \frac{1}{U_1}\frac{dU}{dt}=\left[\frac{t}{(1+t)}\right]\frac{dE_1}{dt}+\frac{dX_1}{dt}+\frac{P_2}{P_1^*}\frac{dX_2}{dt}+\frac{P_3}{P_1^*}\frac{dD_3}{dt}$$

With the imposition of the tariff, P_1 is replaced by P_1^* in (15), so that

$$(21)\quad P_1^*dX_1+\beta P_2dX_2+\lambda P_3dX_3=0$$

Dividing through (21) by P_1^*dt, substituting for dX_1/dt in (20) and with some manipulation, we obtain

$$(22)\quad \frac{1}{U_1}\cdot\frac{dU}{dt}=\frac{1}{1+t}\left[P_1t\frac{dE_1}{dP_1^*}+P_2\frac{dX_2}{dP_1^*}(1-\beta)+P_3\frac{dD_3}{dP_1^*}(1-\lambda)\right]$$

Equation (22), which indicates the effects of a change in the tariff rate on welfare, may

hypothesis. Similarly, in Canada the wage increases secured by unions in the housing industry have far outpaced the increases in other sectors, some of which do enter international trade. Thus, if there was no wage differential in the economy before, one will now be created in such a way that higher wages will be paid by the nontraded good sector.

now be utilized to derive the following results:

1. To begin with, consider these effects in the absence of the wage differential, so that with $\beta=\lambda=1$, (22) reduces to

$$\frac{1}{U_1}\frac{dU}{dt}=\frac{P_1 t}{1+t}\cdot\frac{dE_1}{dP_1^*} \tag{23}$$

In the absence of nontraded goods, $dE_1/dP_1^*<0$, that is, a rise in the domestic price of the importable good resulting from the rise in tariff lowers the demand for imports, so that $(1/U_1)(dU/dt)<0$. In other words, a rise in the tariff rate leads to a decline in welfare. This is the standard theorem derived by Kemp. However, when a nontraded good is introduced, the sign of dE_1/dP_1^* becomes ambiguous, because now the repercussions of a change in the domestic price of the importable good on the price of X_3 have also to be considered. Even if all goods are assumed to be gross substitutes, Komiya has shown that the sign of (dE_1/dP_1^*) may be uncertain, simply because of the ambiguity in the sign of (dX_1/dP_1^*), which is possible when a third, nontraded good is incorporated into the model. Thus we conclude that the effects of a rise in the tariff rate on social welfare are uncertain in the presence of the nontraded good. *What is of great interest is that a higher tariff may lead to higher welfare than a lower tariff in the presence of the nontraded good, in spite of the absence of the wage differential, so that the standard theorem by Kemp may not hold.*

2. When wage differentials are also introduced, (22) shows that the sign of $(1/U_1)(dU/dt)$ becomes ambiguous even if (i) $(dE_1/dP_1^*)<0$, (ii) $(dX_2/dP_1^*)<0$ and (iii) $dD_3/dP_1^*>0$, so that all goods are gross substitutes. The increase in the tariff rate may or may not cause a decline in welfare. Here again by following the procedure established in the previous section, one can demonstrate the significance of factor proportions in the three industries for the change in welfare when the higher wage rate is paid by the import-competing industry. The interested reader can derive his own conclusions with the help of condition (19).

If the wage differentials exist among all three industries, the results derived above may be strengthened or weakened. Again it may be noted that the effects of the wage differential may cancel out and the last two terms in the square brackets of (22) may add to zero. But the standard theorem by Kemp may still be invalid because of the possibility of the positive sign of (dE_1/dP_1^*).

IV. Free Trade Versus No Trade and Optimum Policy

In the last section we have shown that there is no monotonic relationship between the tariff rate and the level of social welfare when the interindustry wage differential is present even if (dE_1/dP_1^*) has the "normal" negative sign. Since free trade represents the absence of the tariff and no trade may be considered to be a situation with prohibitive tariff, the results derived in the previous section are applicable to the questions under consideration in the present section. In the absence of the monotonic relationship between the rate of tariff and social welfare, we conclude that in the presence of the interindustry wage differential, free trade may or may not be superior to no trade.[5]

In other words, the Bhagwati-Ramaswami theorem continues to hold when a nontraded good is introduced in their model incorporating factor market imperfections, although their condition that the wage differential should be paid by the importable good ceases to be the necessary condition,[6] for the sign of

[5] It is worth pointing out here that this procedure does not apply to the case where the wage differential does not exist. As shown above, (22) now reduces to $(1/U_1)(dU/dt)=(P_1t/1+t)(dE_1/dP_1^*)$, and the ambiguity in the sign of (dE/dP_1^*) in the presence of the nontraded good may lead one to the faulty conclusion that free trade may be inferior to no trade. In the subsequent sections free trade is shown to be the optimal policy in the absence of the wage differential regardless of the presence of nontraded goods. A simple proof of this result actually follows from (23) if we assume that there is no tariff in the initial situation, so that $t=0$ and with $\beta=\lambda=1$, $(1/U_1)(dU/dt)=0$. In the presence of the wage differential, however, it is easily seen that this is not true.

[6] The earlier trade literature on wage differentials has

$(1/U_1)(dU/dt)$ turns out to be indeterminate if the differential is paid by only the nontraded good. This brings us directly to the question of optimal policy in the presence of the wage differential and the nontraded good. Here it is fruitful to draw a distinction between the optimal policy in the presence of a stable interindustry factor-price differential, which we shall call the second best policy, and the optimal policy that serves to eliminate the factor-price differential to the producers, so that the *optimum optimorum* is achieved. This latter policy will be referred to as the first best policy. Assume that initially there is free trade. Differentiating (1)–(5) totally and following essentially the same procedure as that used in Section II, we obtain

$$\frac{dU}{U_1} = \frac{P_2}{P_1} dX_2(1-\beta) + \frac{P_3}{P_1} dX_3(1-\lambda) \tag{24}$$

The following results are then immediate:

1. The necessary condition for an interior maximum is that $(dU/U_1)=0$. If the wage differential does not exist so that $\beta=\lambda=1$, this condition is automatically satisfied. In other words, free trade is the first best policy in the absence of the distortionary wage differential even when a nontraded good is introduced.

2. If the nontraded good does not exist, then $(dU/U_1)=P_2dX_2(1-\beta)/P_1$. Here β reflects the divergence between the marginal rate of transformation and the international-price ratio, because from (15*) $(dX_1/dX_2) = -(\beta P_2/P_1)$ when the nontraded goods are absent. The optimal policy in the presence of the wage differential requires a change in X_2 such that the divergence between the marginal rate of transformation and the given international-price ratio is eliminated, so that the value of β to the producers comes to equal unity. The second best policy in other words requires the imposition of a production-tax-cum-subsidy on second commodity. This result is also due to Bhagwati and Ramaswami. The first best policy, of course, consists in the elimination of the effective wage differential to the producers by means of the factor tax-cum-subsidy policy, such that (α_1/α_2) and β are equated to one. This is the proof of the first best policy prescribed by Bhagwati and Ramaswami.

3. Suppose the nontraded good exists. Then if the wage differential is paid either by the nontraded or the exportable good, so that only β or λ differs from unity, the second best policy requires respectively the imposition of the production tax-cum-subsidy on the second commodity, or a *consumption subsidy* on the third commodity such that the divergence to the producers between $-(dX_1/dX_2)$ and

$$[(P_2/P_1)(1 + (P_3/P_2)(dX_3/dX_2)]$$

is eliminated, that is to say, the effective value of β or λ, as the case may be, is equalized to unity. Note that when the differential is paid by the nontraded good, the second best policy calls for the grant of a consumption subsidy to the domestic good, a policy that does not apply to the case of traded goods. Since the distortion is in the domestic production sector of the economy, the thrust of the cure should also lie in re-

tended to make an illusory distinction between a wage differential which leaves the pattern of trade unchanged and one that causes a change in this pattern. With the former type of wage differential, the beneficent effects of free trade continue to exist, whereas with the latter type, they may not (see Everett Hagen, Bhagwati and Ramaswami, etc.). However, it appears that this is an unsatisfactory way of presenting the conclusions, for whether or not the differential causes a reversal in the earlier pattern of trade, there are always two possibilities, namely, 1) the differential is paid by the exportable good, and 2) it is paid by the importable good. Suppose in the absence of the wage differential, one commodity is imported, and suppose now that the differential is introduced which is unfavorable to this importable good. Obviously, the earlier pattern of trade cannot be reversed in this case. The conventional literature would then create the impression that the standard theorems will now be valid because the earlier pattern of trade is not reversed, which is not true. One does not have to bother about the reversal of the pattern of trade. In a two-good model, as stated above, there are only two possibilities: under one the traditional results hold, under the other, they may not. In this paper, this is how the conventional results and our own results have been presented.

moving the inequality between $-(dX_1/dX_2)$ and $(P_2/P_1)[1+(P_3/P_2)(dX_3/dX_2)]$. Just as in the two-good model, the second best optimum is achieved by changing the output of X_1 and X_2 in such a way that the difference between $-(dX_1/dX_2)$ and (P_2/P_1) is eliminated. If the consumption tax (or subsidy) were to be imposed on one of the traded goods, there will not be any change in outputs, for (P_2/P_1) which is exogenously determined will remain unchanged for the producers. However, in the case of the nontraded good, the domestic output of X_3 equals its domestic consumption. Therefore, if the wage differential is paid by X_3 producers, the second best optimum will be attained only by increasing its output to such an extent that to its producers λ comes to equal unity. However, in order to raise the output of X_3 without creating a discrepancy in its domestic demand and supply, a consumption subsidy to the nontraded good, rather than a production subsidy, is required. The output of X_3 will automatically rise when its demand increases, for in the three-good, two-factor model, as demonstrated by James Melvin and Kemp, any number of output configurations are compatible with a given set of commodity prices. The production possibility surface is completely described by straight lines and each line is a locus of possible output configurations for the three commodities corresponding to a given set of commodity prices. Hence when a consumption subsidy is given to the nontraded good, a new production point can be selected for the given set of prices in such a way that $P_1dX_1+P_2dX_2+P_3dX_3=0$. It may also be noted from (24) that when $\lambda<1$, so that the wage differential is paid by the nontraded good, a positive sign of $dD_3=dX_3$ will raise welfare.

On the other hand, if a production subsidy was granted to the nontraded good, the change in its output would not necessarily be matched by the change in its consumption, so that a disequilibrium situation could arise which will not be self correcting because the price of the nontraded good to the consumers remains constant under the small country assumption.

4. Finally, if the wage differential is paid by the importable good, then, given that the nontraded good exists, both β and λ exceed unity. An interesting but chance result emerges here. It is possible that $(dU/U_1)=0$, provided $P_2dX_2(1-\beta)+P_3dX_3(1-\lambda)=0$, or

$$\frac{P_3(1-\lambda)}{P_2(1-\beta)}=\frac{dX_2}{dX_3} \tag{25}$$

In this case free trade alone is the second best policy and the imposition of the production tax-cum-subsidy is not needed. Although this result is purely of academic interest, for only by coincidence will β and λ be such as to satisfy (25), yet the condition does suggest an interesting possibility. In any case if the difference between the left- and right-hand sides of (25) is small, the gain to be derived from the introduction of the production tax-cum-subsidy may not be more than negligible and may not be worth the administrative headaches and costs. A necessary condition for (25) to be satisfied is that (dX_2/dX_3) be positive, because both β and λ exceed unity when the differential is paid by X_1 producers. The chances of (25) being satisfied improve if the differential exists among all three industries so that $\alpha_1\neq\alpha_2\neq\alpha_3$; nor is it necessary anymore that (dX_2/dX_3) be positive, because it is possible that $\lambda\lessgtr 1$ when $\beta\gtrless 1$. The interesting point is that there exists a certain configuration of wage differentials which will satisfy (25). Nevertheless, in all the cases discussed above, the first best policy requires the use of factor tax-cum-subsidy so that the differential to the producers is eliminated.

An interesting policy device to attain the second best welfare suggests itself from this discussion. Suppose the level of the inter-industry factor-price differential itself depends on the government policy. For example, Harry Johnson, referring to Arnold Harberger, has suggested that the inter-industry factor-price differential will occur if the government imposes a corporation income tax (which is a tax on the use of capital in the corporate sector alone), that drives a wedge between the gross rewards of capital

in the corporate and the noncorporate sector. If the government must impose the corporation income tax in order to raise revenue, etc., it could be imposed in such a way as to satisfy condition (25). For a small country, the commodity prices and hence factor-proportions and f_2 and f_3 are given. All we then need to do is to select that level of tax on the use of capital, and hence the level of λ and β, such that $(1-\lambda)/(1-\beta)$ is equated to $P_2f_2(k_3-k_1)/P_3f_3(k_2-k_1)$, because from (12) $(dX_2/dX_3)=f_2(k_3-k_1)/f_3(k_2-k_1)$. Although λ and β represent the wage differential among the three industries under the assumption of similar reward of capital in all industries, the arguments are little modified if the rewards of capital differ among industries but the wage rates are similar.

Optimal Effective Protection in General Equilibrium

By Francisco R. Casas*

In a well known article, Roy Ruffin has shown that for a small country importing a final as well as an intermediate product, the second best optimum effective tariff rate using the Barber-Johnson-Balassa measure is zero when the imported input is not produced domestically and is used in the import-competing sector only.[1] Ruffin defines the second best optimum in terms of a given consumption distortion. It will be shown, however, that the optimality of a zero effective tariff rate is not unambiguous in terms of a given *production* distortion and that, in fact, there exist two different second best optima in this context.

Following Ruffin, it will be assumed that the home country is small and produces two final goods, X_1 (exportables) and X_2 (importables). The production of import-competing goods requires the use of an imported material input, X_3, which is not produced domestically and which is used in fixed proportions. Production functions are homogeneous of the first degree and quasi-concave, and all competitive assumptions are assumed to hold. To avoid income distribution problems, we postulate a collective utility function $U=U(C_1, C_2)$, where C_i is the aggregate consumption of the ith good. With p denoting the relative price of the second commodity in the home country, X_1 being taken as the numeraire, changes in real income or welfare measured in terms of the numeraire are given by[2]

$$dy = \frac{dU}{U_1} = dC_1 + pdC_2 \tag{1}$$

Let p^* denote the fixed foreign price ratio of final commodities, p_3 and p_3^* the domestic and foreign relative price of the intermediate good, respectively, and k the fixed intermediate input coefficient in the import-competing sector. Balanced trade then implies

$$E_1 + p^*E_2 + p_3^*kX_2 = 0 \tag{2}$$

where $E_i=C_i-X_i$ is the domestic excess demand for the ith good. From (1) and (2), the change in welfare for small changes in p, p_3, and X_i that satisfy the budget constraint is readily shown to be given by

$$\begin{aligned} dy = [&dX_1 + (p - kp_3)dX_2] \\ &+ k(p_3 - p_3^*)dX_2 \\ &+ (p - p^*)dE_2 \end{aligned} \tag{3}$$

Since along the production possibility curve the marginal rate of transformation between the two final goods equals the ratio of value-added, the first bracketed term on the right-hand side of the above equation is zero. On the other hand, if t and t_3 denote, respectively, the ad valorem tariff rates on imports of the final and the intermediate goods, then $p=p^*(1+t)$ and $p_3=p_3^*(1+t_3)$. It follows that

$$dy = kt_3p_3^*dX_2 + tp^*dE_2 \tag{4}$$

Substituting for dE_2, we now obtain

$$dy = -p^*(t-\theta_3t_3)dX_2 + tp^*dC_2 \tag{5}$$

where $\theta_3=kp_3^*/p^*$ is the distributive share of the material input at free trade prices.

This last expression for the change in welfare may be further simplified by noting that the domestic output of the importable good, X_2, is a function of p and p_3, and that

* Department of political economy, University of Toronto. I am indebted to James R. Melvin, J. Clark Leith, and an anonymous referee for their valuable comments on the initial draft of this paper.

[1] Ruffin also showed that the second best optimum rate of effective protection is zero when the imported input is used in the export sector or in both sectors provided another unbiased measure of effective protection which he proposes is adopted. However, we shall not be concerned with this problem here.

[2] The reader will recognize the technique used by Ronald Jones.

$(\partial X_2/\partial p_3) = -k(\partial X_2/\partial p)$.[3] It can thus be seen that

$$(6) \quad dX_2 = \frac{\partial X_2}{dp} \cdot \frac{dp}{dt} dt + \frac{\partial X_2}{\partial p_3} \frac{dp_3}{dt_3} dt_3 = p^*(dt - \theta_3 dt_3) \frac{\partial X_2}{\partial p}$$

On the other hand, C_2 is a function of the commodity price ratio, p, and real income:

$$(7) \quad dC_2 = \frac{\partial C_2}{\partial p} \frac{dp}{dt} dt + \frac{\partial C_2}{\partial y} dy = p^* \frac{\partial C_2}{\partial p} dt + \frac{m_2}{p} dy$$

where m_2 is the marginal propensity to consume importables in the home country. Substituting for dX_2 and dC_2 in equation (5) yields equation (8).

$$(8) \quad dy = \frac{p^{*2}(1+t)}{(1+m_1 t)} \cdot \left\{ -(t - \theta_3 t_3) \frac{\partial X_2}{\partial p} (dt - \theta_3 dt_3) + t \frac{\partial C_2}{\partial p} dt \right\}$$

where

$$m_1 = 1 - m_2, \quad \frac{\partial X_2}{\partial p} > 0; \quad \text{and} \quad \frac{\partial C_2}{\partial p} < 0$$

Consider first the case analyzed by Ruffin in which a tariff on the final good is arbitrarily set ($t = \bar{t}$) and the problem is then to find the second best optimum tariff on the imported input, $t_{3,op}$. In this case, we can write

$$(9) \quad \left.\frac{\partial y}{\partial t_3}\right|_{t=\bar{t}} = \frac{p^{*2}(1+\bar{t})}{(1+m_1\bar{t})} \cdot \left\{ (\bar{t} - \theta_3 t_3) \frac{\partial X_2}{\partial p} \cdot \theta_3 \right\}$$

[3] As long as X_1 does not use the imported input, the output of X_2 is a monotonically increasing function of $(p - kp_3)$.

If t_3 is at its optimum value, $\partial y/\partial t_3 = 0$, so that

$$(10) \quad t_{3,op} = \bar{t}/\theta_3$$

Remembering that the Barber-Johnson-Balassa measure of effective protection is $ERP = (t - \theta_3 t_3)/(1 - \theta_3)$, it follows that for any given $\bar{t}$, the optimum effective rate of protection is

$$(11) \quad ERP_{op} = \frac{[\bar{t} - \theta_3(\bar{t}/\theta_3)]}{(1 - \theta_3)} = 0$$

which is the result derived by Ruffin.[4]

It must be noted that this result was derived under the assumption that the first best optimum solution (namely, free trade) is not attainable because of the presence of a nominal tariff on the final commodity. The question arises, however, as to whether the second best effective tariff rate is zero when the initial distortion is a nominal tariff on the imported intermediate good. Let $\bar{t}_3$ be any such arbitrarily chosen tariff; the effect of imposing a tariff on the final commodity is now given by

$$(12) \quad \left.\frac{\partial y}{\partial t}\right|_{t_3=\bar{t}_3} = \frac{p^{*2}(1+t)}{(1+m_1 t)} \cdot \left\{ -(t - \theta_3 \bar{t}_3) \frac{\partial X_2}{\partial p} + t \frac{\partial C_2}{\partial p} \right\}$$

It follows that the second best nominal tariff on the final good is

$$(13) \quad t_{op} = \frac{\theta_3(\partial X_2/\partial p)\bar{t}_3}{(\partial X_2/\partial p) - (\partial C_2/\partial p)} \gtrless 0 \quad \text{if } \bar{t}_3 \gtrless 0$$

and the second best effective rate of protection is

$$(14) \quad ERP'_{op} = \frac{\theta_3(\partial C_2/\partial p)\bar{t}_3}{(1-\theta_3)[(\partial X_2/\partial p) - (\partial C_2/\partial p)]} \lessgtr 0 \quad \text{if } \bar{t}_3 \gtrless 0$$

In other words, *given any arbitrary tariff (subsidy) on the material input, the second best effective tariff rate is negative (positive)*!

[4] See his equations (5) and (9), pp. 264–65.

This result stands in sharp contrast with Ruffin's and is indeed odd. However, the intuitive explanation of this asymmetry between the two cases is quite simple. The initial imposition of a tariff on imports of the final good results in a production loss as well as a consumption loss. When a tariff on the imported input is then levied, the effect of the latter is to reduce the production loss as the output bundle produced moves toward its free trade composition, while the original consumption loss remains unaffected. When the effective tariff rate falls to zero the production loss will have been totally eliminated and further increases in t_3 will again result in production losses.[5]

On the other hand, the initial imposition of a tariff on the intermediate good involves only a production loss. If a tariff on the final commodity is subsequently introduced, this production loss is reduced but a consumption loss is simultaneously created. Thus, it is no longer clear that the attainment of the second best optimum involves raising the tariff on the final good up to the point where the effective rate of protection is zero, i.e., up to the rate at which the production bundle is the same as under free trade. In fact, the optimum *ERP* will always be negative in this case[6]—expect in the event that the two final goods are consumed in fixed proportions ($\partial C_2/\partial p=0$) or if $\partial X_2/\partial p$ approaches infinity. Conversely, if the import-competing sector is being protected through a subsidy towards the use of the material input, the second best policy involves an output tariff which is not large enough to wipe out the protection given to that sector.

Thus, it turns out that we cannot in general conclude that the second best rate of effective protection is zero in the small country case. This will be true if the exogenous distortion takes the form of nominal protection of the import-competing industry, but not if the distortion is a tariff or subsidy on the imported input used by that industry. This, in turn, casts some doubt on Ruffin's definition of an *efficient* measure of effective protection: " . . . if when the effective tariff on the imported final good is zero and the tariff on the final good is non-zero, a second best optimum is achieved, then the effective tariff is said to be *efficient*" (p. 265). While Ruffin argues that the Barber-Johnson-Balassa measure is efficient, at least for the case where the commodity using the imported material input is itself an importable good, we have shown that this definition holds only if additional qualifications are made, namely, a specification of the nature of the initial distortion. Indeed, it appears that no measure of effective protection can be devised that will be unambiguously "efficient" in this sense and the concept of efficiency is thus of limited use for practical policy making.

[5] This brings out the point—not always explicitly recognized—that there are production losses from too much specialization as well as from too little.

[6] The reader may wonder whether it is not possible for the additional consumption losses from successive increases in t to be so small as to make it profitable to raise the latter to the point where the $ERP=0$. However, we must note that reductions in production losses are proportional to the effective rate of protection $(t-\theta_3\bar{t}_3)$ while increases in consumption losses are proportional to the nominal tariff rate t. Thus, for any non-extreme values of $\partial X_2/\partial p$ and $\partial C_2/\partial p$, it will always be true that for t sufficiently close to $\theta_3\bar{t}_3$, $-(\partial X_2/\partial p)\cdot(t-\theta_3\bar{t}_3)>-(\partial C_2/\partial p)t$.

Industrial Prices, as Administered by Dr. Means

By GEORGE J. STIGLER AND JAMES K. KINDAHL*

The most fundamental proposition in the administered price literature is that prices in industrial markets, especially those which are oligopolistic in structure, are unresponsive to changes in general business conditions, and that this behavior is pervasive. Our study, *The Behavior of Industrial Prices*, is an examination of the evidence regarding this view.

Our central purpose was to ascertain whether "administered prices" which, as reported by the Bureau of Labor Statistics (*BLS*), were essentially unresponsive to declines of general business conditions, were in fact unresponsive: that is, our central task was to obtain transaction rather than quoted prices. To that end, we collected buyers' prices on commodities that met two conditions:

i. The commodities were those which did not undergo large quality changes over cycle-length periods of time (so the prices would be meaningful), and

ii. The prices were generally considered to be administered.

It follows that we were making a one-way test of the existence of administered prices: we deliberately omitted all industrial prices where the phenomenon of administration had not been urged with some plausibility. This concentration on administered prices had only three possible (but by no means certain) exceptions of which we were aware: bituminous coal, wood flooring, and plywood, where excellent price series became available.

The concentration of the sample in the area of administered prices means, of course, that we were not searching the universe of industrial prices to determine the extent of "administration" but rather that we were examining the behavior of so-called administered prices. Even if 100 percent of our sample showed a particular type of perverse price behavior, that would leave open the question of how the remainder (81.1 percent by weight) of nonagricultural and nonfood wholesale prices behaved.

Gardiner Means has reinterpreted the evidence on pricing behavior presented in our book and he is duly rewarded for his diligence by finding that "the administered-price thesis" is fully confirmed (1972). We shall restrict our comments to 1) the criteria of administered prices, and 2) several general questions of empirical procedure; these are the basis for Means' dissent from our conclusions.

I. Means' Concepts of Price Administration

Means has great claims to initiating the literature of administered prices (although F. C. Mills' claims are not negligible), but it is not his personal prerogative to designate which prices are administered in the eyes of the economics profession. The very success of Means' writings—and we reckon him among the most influential of economists in the history of this country—implies that they no longer have any special meanings he might wish to attach. For scientific purpose, it is the accepted view of administered prices that must prevail. Most economists specializing in industrial organization will accept our list of administered prices as generally valid (although incomplete).

Of course we concede Means' right to define administered prices for himself as he wishes, and we would be glad to segregate out a subset of prices and label them "Means-administered," but this proves to be virtually impossible—at least for us. It will be useful to comment upon his changing criteria of administration.

Initially his definition of administered prices was as follows:

> A market price is one which is made in a market as the result of the interaction of buyers and sellers. The prices of

* University of Chicago and University of Massachusetts, respectively.

> wheat and cotton are market prices. . . .
>
> An administered price is essentially different. It is a price which is set by administrative action and held constant for a period of time. We have an administered price when a company maintains a posted price at which it will make sales or simply has its own prices at which buyers may purchase or not as they wish. [1935, p. 1]

This distinction is palpably vague. Even on an organized exchange a buyer or seller may have a bid or ask price which persists for a long time. Conversely, what if one of numerous firms in an industry changes prices each month, but it is a different firm each month—the *BLS* data often display this amazing behavior—is the *market* price administered? Or if the firm makes different offers for forward contracts of different length—is its price constant over time?

In his actual practice during the 1930's, Means defined administration as infrequency of price change, and measured it simply by frequency of price change per price reporter. Thus, if three sellers of a product each made one price change in a three-year period, the price flexibility measure would be 1/35 whether the changes were in the same month or different months. The literature of economics did not faithfully follow Means in this respect; it introduced two different criteria which are absent from his early work:

i. Oligopoly or high concentration was identified with administration; Means expressly disavowed this connection.[1]

ii. Frequency of price change received less emphasis, partly as a result of the increased attention to concentration, in favor of amplitude of price change.

When Means applied himself to inflationary conditions in the 1950's, he modified his criteria in several respects:

i. He necessarily used the inappropriate *BLS* frequency of price change, whose behavior is strongly influenced by the number of price reporters.[2] Hence, measured frequency of price change became heavily dependent upon the number of price reporters.

ii. He modified the classification resting upon frequency of price change in a highly subjective fashion:

> The classification of price groups into those dominated by price administration, mixed, and those dominated by market prices is based upon general knowledge. It is consistent with the findings of the BLS on average frequency of price change except in the five cases [out of a total of 15] as is shown in the table below: . . . [1959, p. 4756].

Here Means was dealing with categories of *BLS* prices rather than individual prices, but the criteria should not be affected.

iii. A tacit acceptance of the congruence of his classification with that of competition and monopoly became apparent, although not wholly explicit. Thus, he refers to "classically competitive prices for food, leather, lumber, textiles, and farm products . . . " (1959, p. 4758, also p. 4775). In the same oral testimony, he says, "I know well that the rubber industry, the manufacturing of rubber, is fairly concentrated. Therefore we could appropriately classify even this exception [the rubber and rubber products industry] as black" [i.e., as an administered price industry; a chart presented had colored industries said to have administered prices in black] (1959, p. 4758).

In his most recent article, Means offers still another criterion of administered prices. He omits fifteen commodities as being market-dominated. Eight copper related prices, for example, are deleted because they are "fabricated from highly competitive raw materials" (1972, pp. 295–96, n.). This is an almost new criterion of nonadministration, wholly absent from his works in the 1930's,

[1] Means, (1935), p. 1: "Administered prices should not be confused with monopoly. The presence of administered prices does not indicate the presence of monopoly. . . . In many highly competitive industries, such as the automobile industry, prices are made administratively and held for fairly long periods of time."

[2] Earlier, he had access to individual price reporter data, and our failure to realize this led to the inappropriate criticism which was withdrawn in the *Journal of Economic Literature*, Sept., 1971, p. 852. The data of the 1953–56 study of the *BLS* are fully vulnerable to these criticisms, see Stigler and Kindahl, pp. 18–20.

but with partial anticipation in his testimony before the Kefauver Committee. Yet even in Means' own terms the omissions are odd: The *BLS* price of copper ingots shows in our 10-year period, subperiods of 33, 13, and thrice of 7 months of price constancy.[3] Aluminum ingot prices behave similarly, though the rigidity is less dramatic.

He also has two new interpretations of the implication of price administration:

1. He now believes that administered prices should be corrected for trend (1972, p. 299). This is a novel departure from previous practice—with important implications.

2. " . . . the administered-price thesis is not concerned with regular seasonal price jumps" (1972, p. 301). This again is a wholly new interpretation.

Means' theory has indeed become difficult to refute or confirm. In the absence of a well-defined set of criteria, and rigorously derived implications, no test can be convincing. Means' criteria have changed—or, perhaps, evolved—over time. The implications have become so broad as to be almost uselessly vague: "Basically, the administered-price thesis holds that a large body of industrial prices do not behave in the fashion that classical theory would lead one to expect." His empirical work using our data embodies this statement without further qualification. We think that virtually all of our price series are appropriate to what economists in general mean by administered prices, and that our interpretation of its implications conform to an important segment of thought on the question. We think that Means' extreme flexibility of concept of price administration does his work a disservice.

A final word on Means' "theory." He has never offered an acceptable theoretical explanation for administered prices (=infrequently changed price quotations) as either a phenomenon of individual business or as a market phenomenon. We provide an orthodox explanation of long-term contracts by individual businesses in our book, and find no clash between traditional theory—once transaction costs are introduced—and observed behavior. Means insists upon limiting "classical" price theory to the large-number auction of a perishable good, and much of his frustration with the theory comes from this narrow vision.[4]

II. The Interpretation of Evidence

Means' paper comes to the conclusion, startling at least to us, that our new price data really indicate the opposite of what we assert: the new data, indeed, seem to him to provide overwhelming support for his administered-price thesis. Thus, his Table 1 retabulates our data to suggest that well over half our price series conform to his "truncated administered-price hypothesis." How can our statistics be truly so obliging to Means' purposes? There are three reasons.

First, he excludes nearly one-fourth of our price series as "raw material dominated" (a concept left undefined). We have already argued that this exclusion is mistaken.

Second, he redates the turning dates of cycles. We adopted the reference cycle dates of the National Bureau of Economic Research (*NBER*)—a chronology which has been widely accepted by the economics profession. For reasons best known to himself, Means constructs new cycle dating by using only his interpretation of the Index of Industrial Production; this gives the same results as the *NBER* dating for the first contraction (July 1957–April 1958) and for the beginning of the first expansion (April 1958); he dates the end of the expansion at June 1959, eleven months short of the May 1960 peak of the *NBER* series. Means dates the second contraction as beginning in January 1960. Thus, he leaves the last six months of 1959 in the limbo of neither expansion nor contraction—a procedure totally foreign to the accepted methods of defining cycles. Finally, he finds the expansion ended in March 1962. (The *NBER* reference cycle expansion does not begin until January 1961).

[3] The Houthakker report on copper prices states that with the pegged domestic price producers "have traditionally attempted to mitigate fluctuations in copper prices by changing prices only at discrete intervals. . . ." (Council of Economic Advisers, p. 9).

[4] Means asserts a clash because he has a rigid, elementary competitive price model (1972) p. 302.

The expansion beginning in 1961 (as seen by the *NBER* reference cycle) is the longest in the history of the United States. We noted that taking the entire period of 1961–66 as an expansion would give so much weight to trend factors as to be useless as a cyclical measure. Somehow, we had to choose part of that expansion for analysis. Means wishes to choose the first 14 months; we chose the last 24. Our grounds were that in the 1961–66 period, a number of indicators (*GNP*, constant dollar *GNP*, industrial production, expenditures on new plant and equipment) showed higher annual percentage increases in the last two years of the period than in earlier years of the expansion. Moreover, inflation began in these latter two years, and we wished to examine both the accuracy of the Wholesale Price Index (*WPI*), and the behavior of "administered" prices, during this period of rising prices.

Third, Means enlarges the predictions for price behavior of the administered-price hypothesis to include *any* departure from strong classical predictions, and his tables are so labelled. Let us rewrite Means' Table 1 with neutral headings breaking the heading "Conforming to the Truncated Administered-Price Thesis" into two parts.

TABLE 1—MEANS' TABLE 1 REARRANGED AND DISAGGREGATED

	1st Contraction July 57–Apr. 58	1st Recovery Apr. 58–June 59	2d Contraction Jan. 60–Jan. 61	2d Recovery Jan. 61–Mar. 62
Price Increased	15	17	12	5
No Change In Price	19	10	14	16
Price Decreased	16	23	24	29
	50	50	50	50

Consider the two recoveries: the decreases of prices in the recoveries account for *more than half* of the 100 observations on Means-defined administered prices in recoveries. These are classified in his tables as "conforming to the truncated administered-price hypothesis." Shall we call this "administered-price deflation"? The extraordinary intellectual imperialism of this label should be clear.[5] Firms using their market power to force prices down during an expansion are not displaying "administered price behavior" to the profession. We are hardly ready to concede this price behavior to be telling evidence in favor of the view that prices of such goods do not fall in contractions and rise only tardily in expansions.

In the two brief contractions allowed by Means, one shows about a third of the prices declining, the other nearly one-half. Considering the shortness of the period (eight and twelve months, respectively) compared with the typical length of contracts used by our buyers (twelve months) we do not find this convincing evidence of price administration—especially since the fifty commodities surviving in the table are all certified to have administered prices.

We shall not subject the reader to our more detailed differences from Means, such as the overrepresentation of steel products in our sample (which seems evident on the basis of *WPI* weights), or their atypical behavior (which seems evident from the charts in our book), or our use of weighted averages in summarizing experience of two cycles. The *facts* on price behavior are at the reader's disposal and he can form his own judgment.

III. Conclusion

The most fundamental proposition in the administered price literature, to repeat, is that industrial markets, especially those which are oligopolistic in structure, are unresponsive in their pricing to changes in general business conditions. Our work seriously undermines this proposition.

[5] Means goes still further: he finds some commodities with a downward trend in price, whose rates of fall in contractions were less than in expansions. By using deviations from trend (shown as "data corrected for trend"), rather than raw data, he converts them to commodities whose prices "rise" (relatively) in recessions, fall in contractions—and then claims these as behaving as administered-price theory predicts! (see Means (1972) p. 299).

The standard theory of pricing shared by virtually all modern economists has serious limitations and unresolved problems. In our study, we lamented our tardy recognition of the fascinating problem of determining the nature of the contracts under which most industrial goods are sold. We analyzed prices in specific cycles, to get wholly obscure results. Cleverer men will find difficulties with the received theory that never occurred to us. But we do not believe that these known and unknown difficulties with received theory are favorable to Means. His theory, if it be a useful one, cannot be, as at times he believes:[6] prices behave differently than most economists believe—that theory has, no doubt, ample content but no direction. He once observed, no doubt whimsically, that "... if one introduces a single administered price into the [Walrasian] system, the equations cannot be solved" (1962, p. 28). The economy is not all that fragile; a single administered price—let it behave as insanely as the Devil can devise—will have a negligible influence. The thesis that modern economics has received from Means, whatever he intended, is that perverse or unresponsive price behavior is widespread. Our study, without benefit even of data from a large or protracted recession, contradicts that thesis.

[6] An amazing example of this Phoenix property of Means' theory is the discussion of "specific cycles"—large changes in output of individual industries. He views as strong confirmation of his thesis the fact that we found very few price increases in these large expansions (there were few sufficiently large contractions in our period). Yet two pages later he asserts that according to his thesis, prices should *rise* in periods of sustained expansion of output! "... A finding of a predominent tendency for prices to rise in this period could not possibly support either thesis as against the other" (1972, p. 299).

Environmental Externalities and the Arrow-Lind Public Investment Theorem

By ANTHONY C. FISHER*

In a recent article concerning the evaluation of public investments Kenneth Arrow and Robert Lind have shown that, as the net returns to an investment of given size are shared by increasingly many individuals, the risk premium for the representative individual vanishes and, more importantly and perhaps surprisingly, the aggregate of these premiums for all individuals also approaches zero.

The purpose of this note is to consider whether, and how, this result and the implied policy of risk-neutrality in the evaluation of public investments might have to be modified where these investments produce uncertain environmental side effects. In particular, suppose that in addition to the direct costs of undertaking a project, already netted out of the returns, there are other, external costs in the form of environmental damages, borne perhaps by a different set of individuals than those who benefit from the project. In what follows, conditions under which this would affect the Arrow-Lind results are defined, and the results appropriately modified. The note is concluded with a discussion of the empirical relevance of key assumptions in the analysis, and some implications for policy.

I

Following Arrow and Lind, let the welfare function for each of n identical individuals be written

$$(1) \qquad W(s) = E[U(A + s\overline{B} + sx)]$$

where welfare W is the expected utility $E[U]$ of (uncertain) income A independent from the particular public investment under consideration, plus the share s of (net) income B from the investment, made up of the expected returns $\overline{B}$ plus a random component x with mean zero. If all share equally in the net returns, then $s=1/n$. Assuming the representative individual is risk averse, there exists a number $k(n)>0$ such that

$$(2) \quad E\left[U\left(A + \frac{\overline{B}}{n} + \frac{x}{n}\right)\right] = E\left[U\left(A + \frac{\overline{B}}{n} - k(n)\right)\right]$$

i.e., the individual is indifferent between accepting the risk x/n and paying the amount $k(n)$.

Arrow and Lind note first that $\lim_{n\to\infty} k(n) = 0$, and then prove that $\lim_{n\to\infty} n\, k(n) = 0$, which is not intuitively obvious. The meaning of this result is that if n is large enough, then only the expected value of net benefits should be taken into account in evaluating the investment—even though each of the affected individuals is assumed to be averse to risk.

Note that costs and returns are finite, and sum algebraically to B. Any part of B that goes to one individual does not go to another, so that as B is (equally) divided among increasingly many individuals, the size of the share going to each decreases. But suppose, as has been suggested, that in addition to the costs already included in B, the investment generates environmental damages, for example air pollution, which can be considered a "public bad" in the sense that what is received by one economic unit does not appreciably reduce what is received by others. To put the matter a bit differently, let $C(m)/m$ be the environmental damages borne by each of m identically affected individuals. Then $dC(m)/dm>0$, i.e., total damages $C(m)$ are increasing with m, per-

* Resources for the Future, Inc. I have benefitted from conversations with Kenneth Arrow, John Brown, and Harl Ryder, and from comments on an earlier draft by Barry Chiswick, Donald Hester, John Krutilla, Howard Kunreuther and Kerry Smith.

haps sufficiently rapidly that $C(m)/m$ remains constant, or even increases, with increase in m.[1] In this not untypical situation, clearly, the stake in the outcome of each of the affected individuals, and therefore also the cost of risk to each, does not decrease with increases in their number—or, of course, in the number of those who benefit.

The implications of this for the cost of risk in the aggregate, and in turn for the social evaluation of the investment, are spelled out in the following exercise within the Arrow-Lind framework.

Suppose, then, there are n individuals who share equally in the net benefit B from an investment, and m (different) individuals who bear equally the environmental damages. An efficient policy is one that maximizes

$$(3) \qquad nE\left[U\left(A + \frac{B}{n} - \frac{\pi}{n}\right)\right]$$

subject to

$$(4) \quad mE\left[U\left(A - \frac{C(m)}{m} + \frac{\pi}{m}\right)\right] \geq mE[U(A)]$$

where π is the total compensation that could be transferred from the n gainers to the m losers and all other symbols are as defined earlier.

Dividing $C(m)$ into two parts, $\overline{C(m)}$ expected costs, and $Z(m)$, a random part with mean $\overline{Z(m)}=0$, (4) can be rewritten as

$$(5) \quad E\left[U\left(A - \frac{\overline{C(m)}}{m} - \frac{Z(m)}{m} + \frac{\pi}{m}\right)\right] \geq E[U(A)]$$

Assuming the representative individual who suffers the damages is risk averse, there is some positive amount he would be willing to pay in order to remove the risk represented by $Z(m)/m$. At the margin,

$$(6) \quad E\left[U\left(A - \frac{\overline{C(m)}}{m} - \frac{Z(m)}{m} + \frac{\pi}{m}\right)\right] = E\left[U\left(A - \frac{\overline{C(m)}}{m} - l(m) + \frac{\pi}{m}\right)\right]$$

where $l(m)$ is the positive amount which would leave him indifferent between paying and accepting the risk. Combining (5) and (6), we have

$$(7) \quad E\left[U\left(A - \frac{\overline{C(m)}}{m} - l(m) + \frac{\pi}{m}\right)\right] \geq E[U(A)]$$

which implies

$$(8) \qquad \pi \geq \overline{C(m)} + ml(m)$$

Since, however, (3) is to be maximized, π must be as small as possible, so that

$$(9) \qquad \pi = \overline{C(m)} + ml(m)$$

Alternatively, B should be undertaken (assuming no constraint on capital) if

$$(10) \qquad \overline{B} - \overline{C(m)} - ml(m) > 0$$

In the absence of individual risk aversion, the cost of risk-bearing $l(m)$ vanishes, leaving the Arrow-Lind result that a project should be undertaken if the expected value of benefits net of all costs is positive. Where environmental losses are collectively borne, and the risk to those who bear them remains significant, then, this result must be adjusted. To the cost of the project must be added not only the expected value of these losses but also the amount that would be required to compensate those who bear the risk. Although information on these magnitudes would ordinarily be difficult to come by, it is at least clear that some adjustment for risk ought to be made.

The result expressed in equation (10) can be generalized rather simply to treat all individuals symmetrically. Proceeding as before, write

[1] As a matter of fact, the analysis that follows requires only that $\lim_{m\to\infty} C(m)/m \neq 0$. One way in which this condition could fail to hold, i.e., in which $C(m)/m$ could approach zero, would be if a variety of other adverse effects of a very large increase in m, not related to the investment externality, were to render the separate effect of the investment negligible.

$$(11) \quad E[U_i(A_i + \overline{B}_i + x_i)] = E[U_i(A_i + \overline{B}_i - k_i)]$$

where U_i is the utility of the ith individual, from preinvestment income A_i, expected investment benefits $\overline{B}_i$ *net* of environmental costs, and a random investment return x_i. Equation (11) says that there is some positive amount k_i the risk-averse individual would pay that would leave him indifferent between paying and accepting the risk represented by x_i. Let T_i be the amount, positive or negative, that could be transferred from each individual and leave him as well off after the project is undertaken as before. In symbols,

$$(12) \quad E[U_i(A_i + \overline{B}_i - k_i - T_i)] = E[U_i(A_i)]$$

Then

$$(13) \qquad T_i = \overline{B}_i - k_i$$

and the project should be undertaken if

$$(14) \qquad \sum_i T_i = \sum_i (\overline{B}_i - k_i) > 0$$

II

One important assumption underlying these conclusions is of course that the environmental damages associated with the investment represent a nonnegligible fraction of the real income of the affected individuals. Were this not the case, i.e., were they in fact negligible, clearly it would matter little that they are not reduced to individuals as they are spread. This suggests that the appropriateness of the adjustment to net benefits for aversion to the risk of environmental damage may be an empirical question. In at least some cases, as where significantly increased mortality rates, or reduced residential property values have been attributed to air pollution, the environmental effects of an investment project may well be large enough to make the adjustment appropriate.[2] In particular, effects that are cumulative, or irreversible, may fall in this category.[3]

Another important assumption is that the risk is not (costlessly) transferable from the affected individuals to the larger community. If private markets for transferring the risk exist, then the Arrow-Lind results follow, as indeed they demonstrate in the first part of their paper—though not with reference to "collective" risk of the sort considered above. The second part, on which this discussion has been based, is designed explicitly to demonstrate the validity of their results precisely when these markets do not exist. The analysis of the preceding section might then be interpreted as an argument for government provision of insurance, where it is not privately available, against the risk of environmental damage.

The difficulty with this approach is that where markets for transferring risk do not exist, presumably this is because the moral hazard is too great, or the cost of making the complicated contracts that would be required is too high, as Arrow and Lind also note. The case for government provision of insurance against the risk of environmental damage then depends in part on the ability of government to reduce the moral hazard, or the transaction costs. One advantage government has, of course, is that it can in effect enroll the entire community in an insurance program, thereby maximizing risk spreading, or what is the same thing, minimizing the cost of risk bearing, as in the Arrow-Lind model. Thus suppose all costs (as well as all benefits) associated with a particular project, including any environmental damages, were made internal to the project in the sense that returns net of all costs were shared equally. In the framework of the analysis of the preceding section, the m affected individuals would not alone bear the cost and the risk, which would be spread, with the benefits, to all members of the community.

A policy to internalize all of the costs of a public project, including in particular the cost of environmental risk, is certainly appealing, and is consistent with economists'

[2] For empirical studies of the health and property losses attributable to air pollution, see Lester B. Lave and Eugene P. Seskin, and Ronald Ridker.

[3] For a discussion of the special implications of irreversible changes for the problem of environmental preservation, see Kenneth Arrow and Fisher.

recommendations for the control of privately generated external costs. The difficulty here again is that an attempt to transfer risk in this fashion is likely to be accompanied by substantial transaction costs, broadly conceived. Suppose, for example, we are considering whether to build a jetport near enough to a residential neighborhood that some people are likely to be affected by noise and air pollution. In order to make these uncertain environmental costs internal to the project in the sense suggested above (and as they have generally not been), costs of education, persuasion, or even coercion might be incurred. This is because some other people (those not in the affected area) presumably benefit from the project so long as the environmental costs are *not* internalized.

Or suppose the question is whether to construct a dam for purposes of power generation, where this construction necessarily results in the flooding of a canyon, obscuring the walls and converting a free-flowing river into a pool. Suppose, further, that river and canyon, if left undeveloped, are capable of providing valuable recreational and scientific services (though perhaps not to the same individuals who would benefit from the dam). It may be difficult, i.e., costly, even for the government, to identify all those who lose as a result of the development, and to measure all of the losses, as would be required under any scheme that seeks to insure equal shares in the gains from the project net of all losses. What these examples suggest is the possibility that the cost of transferring the risk of some environmental damages from private individuals to the larger community may exceed the cost to these individuals of bearing the risk, where the damages would be hard to identify and measure, or are unequally distributed.

As a final point, note that the suggested transfer will be effective in reducing the cost of risk only if m is small relative to n, assuming again that the environmental costs to each of the m affected individuals are not reduced with increases in m.

What are the implications for policy of the several points raised in the note? First, it would be desirable to internalize, in such a fashion that they are shared more or less equally, the environmental costs of a public project. This is so not only for the traditional reason for internalizing all costs of a private project, namely to correct the distortion in allocation that would result from a failure to internalize, but also for another reason: to eliminate the deadweight loss that would result from privately borne risk of environmental damage. Second, the attempt to transfer this risk to the larger community may itself carry costs; and third, where these (transaction) costs are large enough that transfer is not profitable, the net benefit from a public project should be adjusted to take account of the attitude of the affected individuals toward the risk of environmental damage.

A Note on Proportionally Distributed Quotas

By Rachel McCulloch and Harry G. Johnson*

Traditional theory has usually condemned trade restriction as an irrational or misguided interference with efficient resource allocation. The two notable exceptions have been the "optimum" tariff and the infant industry argument for protection. More recently, however, trade theorists have begun to investigate the possibility that tariffs are used to achieve certain "noneconomic" objectives, that is, ones reflecting considerations not captured by individual private consumption.[1] Their work has evaluated the relative efficiency of tariffs, production subsidies, and consumption taxes as instruments for implementing such objectives as a given increase in domestic production or restraint of imports below the free trade level.[2] This note seeks to extend the analysis by comparing a tariff (or equivalent quota) with a commonly used protective arrangement which we term a "proportionally distributed quota," as alternative means of pursuing various objectives of trade restriction.

We do not intend to de-emphasize the cost, even when minimized, of achieving certain objectives through protection. Rather, to the extent that these objectives are the end result of a process of political bargaining, they may be difficult to alter merely through demonstration of their welfare cost to the economy as a whole. Of course, calculation and promulgation of this cost makes it harder for special interest groups to obtain economic privileges at the expense of the majority. However, we should not overlook the possibility that certain noneconomic objectives are truly public goods which provide sufficient collective utility to the majority to justify their cost in terms of foregone consumption. In either case, it is desirable to provide the least-cost method of achieving the objective. For purposes of this paper, noneconomic can best be understood as "outside the model."

It is well known that any protective goal can be achieved through some combination of a consumption tax and a production subsidy. However, tariffs and quotas are employed much more frequently than direct subsidies—probably for reasons of political feasibility. In this paper we use a familiar model to show that a proportionally distributed quota implies a smaller tax and larger subsidy than a tariff or conventional quota, and thus provides a more economically efficient—but equally practical—means of achieving some objectives.

As long as markets remain competitive, import quotas distributed in most of the usual ways[3] are analytically equivalent to tariffs, since they will acquire a premium value in the market reflecting the domestic scarcity of the importable good.[4] The only difference is in the distribution of the proceeds. In fact, the import licenses can be auctioned to the public, in which case (assuming again that markets remain competitive and in particular that the supply of licenses is not monopolized) the distribution of the proceeds is also equivalent, since the auction should yield the same revenue as would be produced by a tariff. We designate this type of restriction below as a tariff/quota.

In contrast, the proportionally distributed quota is a system in which import rights are assigned to producers or consumers *in proportion to* their individual production or consumption of the restricted good. We show below that *which* group receives the licenses is irrelevant to the resulting equilibrium, for a given objective of protection (again, markets remaining competitive). This is analogous to the fact that the economic incidence

[3] That is, *other than* in proportion to consumption or production.

[4] Bhagwati gives an extended discussion of equivalence under alternative market conditions.

of an excise tax or subsidy does not depend upon its legal incidence. Examples of proportionally distributed quotas are the *U.S.* oil import program, in which quotas are (or were) assigned to refiners in proportion to their refinery throughput,[5] and the system of content protection, by which import duties on parts or finished products or both are waived if a certain percentage of sales is accounted for by domestic value-added.[6]

For simplicity, we assume competitive markets and abstract from the possibility of a quota-induced change in market structure. We also exclude optimum tariff considerations by assuming a perfectly elastic foreign supply curve for the protected good, and ignore the problems raised by divergence between private and social costs or benefits. These complications will be briefly discussed later. We consider four possible noneconomic objectives of trade restriction: (a) to achieve a given ratio (below the free trade level) of imports to domestic production (or, equivalently, consumption); (b) to reduce imports; (c) to increase domestic production; and (d) to reduce domestic consumption. The first of these objectives has increasingly come to be regarded by protectionists as a "fair" compromise between the desire to protect domestic industry from foreign competition and the claims of foreign producers to access to domestic markets (or, possibly, fears on the part of exporters that trading partners may impose retaliatory restrictions). Most protective policies can be expressed in terms of one of these four alternatives.

In the accompanying figures, *DD* is the domestic demand curve for the protected good, *SS* the domestic supply curve, and P_f the world market price of imports. Figure 1 illustrates the standard cost of protection argument,[7] where a tariff or quota restricts imports to a level *FG*. We may define consumption cost to be *GHJ*, production cost to be *FKL*, and observe that tariff revenue (or proceeds from auction of import licenses) is *FGJK*. According to this analysis, the importing country is now worse off than under free trade. However, if we assume that the government behaves rationally, some further policy objective must underlie the restriction of trade, and this should be taken into account in evaluating the result. In terms of the four policy objectives suggested above, the protection imposed is consistent with: a) a desired ratio $k=XV/OX$ of imports to domestic production; b) a reduction of imports to *FG;* c) an increase of domestic production to *OX;* or d) a reduction of consumption to *OV*. We will compare the cost of achieving each of these objectives through a tariff/quota with that incurred when a proportionally distributed quota is used. The difference results from the fact that the proportionally distributed quota uses the value of the import licenses to influence directly the allocation of resources within the protected industry. In some instances, this reduces the degree of import restriction (and hence the welfare cost) required to achieve the desired result.

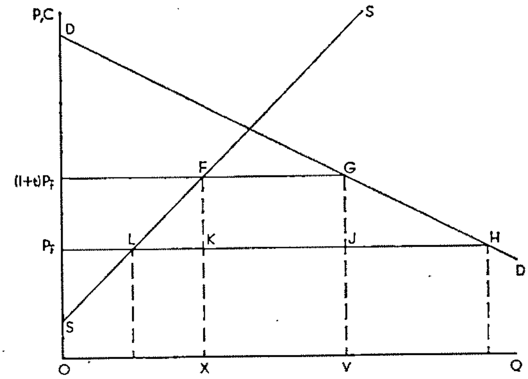

FIGURE 1. THE COST OF PROTECTION

Suppose that the policy objective is (a), a given ratio of imports to domestic production. Assume now that import licenses are distributed to each producer in proportion k to his individual output. This will cause domestic output (and hence imports) and consumption to increase above their levels under the tariff/quota used to achieve the same objective. To see why this occurs, con-

[5] For a detailed description of the mechanics of the program, see the Cabinet Task Force on Oil Import Control.

[7] See, for instance, Charles P. Kindleberger, pp. 105–06.

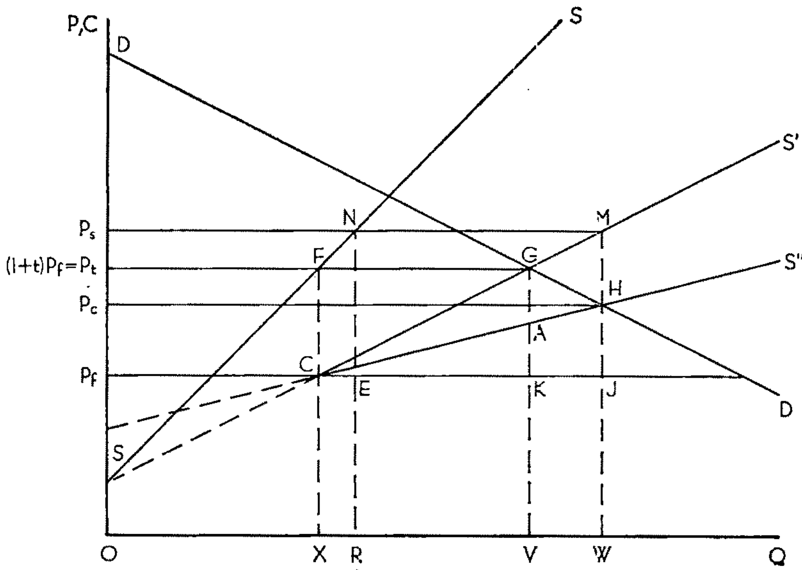

Figure 2. A Fixed Ratio of Imports to Domestic Production or Consumption

sider the position of producers at the tariff/quota equilibrium point, G, reproduced in Figure 2. The value of each license is $P_t - P_f$, the difference between the cost of importing an additional unit and the price which consumers are willing to pay for it. Receipts from an additional unit produced will be the market price P_t plus the value of the fractional import license thus earned, a total of $P_t + k(P_t - P_f)$. This exceeds the domestic producers' supply price, P_t. Therefore, production (and consumption) will be expanded until, at the new equilibrium point, H, domestic supply price P_s exceeds demand price P_c by exactly the value of the fractional import license earned by an additional unit of domestic output:

$$P_s - P_c = k(P_c - P_f)$$

Since consumption is equal to domestic production plus imports, the induced change in production is related to the increase in consumption by

$$(1 + k)(P_s - P_t)\frac{\Delta Q_s}{\Delta P_s} = (P_c - P_t)\frac{\Delta C}{\Delta P_c}$$

Use of a proportionally distributed quota results in a new relationship linking P_c, P_s, and P_f, which may be considered the *net* marginal cost or supply price of the producer-importer. An additional unit of domestic production, along with exercise of the import privilege thus earned, increases total cost by $P_s + kP_f$ and total supply by $1+k$ units. Hence, the net marginal cost of the protected good when supplied under the constraint of a fixed proportion of imports to domestic production is

$$\frac{P_s + kP_f}{1 + k} = \frac{1}{1 + k}P_s + \frac{k}{1 + k}P_f$$

This net supply relation is shown as the schedule S'' in Figure 2. The S'' schedule begins at point C of Figure 2, since for domestic prices less than P_f there would be no imports. As a consequence of competitive profit maximization, the net supply price must equal the market demand price, so that

$$P_c = \frac{P_s + kP_f}{1 + k}$$

i.e., the new equilibrium, H, is at the intersection of the S'' schedule with the domestic demand curve.

The S'' schedule (for domestic prices

above P_f) is the weighted average of foreign and domestic supply cost, the weights being the proportion of each in total consumption. To disaggregate this average, the S' schedule can be used. For every domestic supply price above P_f, the S' schedule shows $(1+k)$ times domestic output. For any level of total supply (consumption), the S'' schedule gives the net social cost while the S' schedule provides the domestic supply price of the required domestic output component of that total.

A proportionally distributed quota results in total consumption of OW of which OR is domestically produced at a supply price of P_s, while RW is imported at the world price, P_f. Total value of the import licenses, $(P_c - P_f)RW$, is equal to $(P_s - P_c)OR$, the excess of total cost of domestic output over its market price.

A tariff/quota is equivalent to a subsidy to production plus an equal tax on consumption. The proportionally distributed quota provides a different "mix" of the tax and subsidy elements. From Figure 2 we can see that a proportionally distributed quota results in an *additional* production subsidy of $P_s - P_t$ over that implied by the tariff/quota, plus a countervailing consumption subsidy of $P_t - P_c$, which partially cancels the consumption-taxing effect of the tariff/quota. The fact that a proportionally distributed quota implies a larger production subsidy and a smaller consumption tax than a comparable tariff/quota indicates that the former will be preferred whenever the consumption-tax aspect is an undesired side effect of achieving the policy objective.

From this, it can be seen that a proportionally distributed quota maximizes welfare subject to the constraint that imports are a fixed proportion of domestic production. The marginal condition for welfare maximization requires that price equal marginal cost. As previously indicated, the effective marginal social cost of the product when supplied under the given constraint is $(P_s + kP_f)/(1+k)$. By using the proportionally distributed quota, we equate this constrained marginal cost to the demand price of consumers. In Figure 2, the welfare gain which results from substituting this method for a tariff/quota is measured by $GHWV - FNRX - (KJWV - CERX) = GHA$. The area $GHWV$ is the gain from increased consumption of VW. The cost is $FNRX$ of additional domestic production and $KJWV - CERX = k(XR)P_f$ of additional imports. Net cost of additional consumption is given by the S'' schedule, so that the cost is also measured by $AHWV$. Thus, the welfare gain is $GHWV - AHWV = GHA$.

We stated earlier that the resulting equilibrium does not depend on whether consumers or producers receive the import licenses. This can be seen easily in terms of the net supply relation derived above. To maintain the same proportion of imports to domestic production, imports must be a fraction $k' = k/(1+k)$ of total consumption. Now consider the effective supply curve facing the consumer. For each unit he consumes, he obtains the right to purchase a fraction k' at the world price P_f. The remaining fraction $1-k'$ must be purchased domestically at the supply price P_s. Thus, the average price per unit is

$$k'P_f + (1 - k')P_s = \frac{k}{1+k}P_f + \frac{1}{1+k}P_s$$

Hence the net supply schedule facing the consumer is exactly that which is obtained when the licenses are distributed to producers. This symmetry does not depend on demand or supply elasticities.[8]

Policy objective (b), a given *level* FG of imports, is analyzed in Figure 3. The value of k is chosen so as to produce the desired equilibrium import level, FG $(=LR)$.[9] As discussed above, the value of the import licenses given to producers in proportion to their individual output results in increased domestic output and consumption. At the proportionally distributed quota equilibrium, R, the excess of total cost of domestic

[8] Although the two equilibria are alike in every *real* way, the domestic price P_c is not the same. Thus, the *nominal* value of the import licenses is also different.

[9] The appropriate value of k in this case is *less than* XV/OX, the proportion of imports to domestic production under a tariff/quota regime.

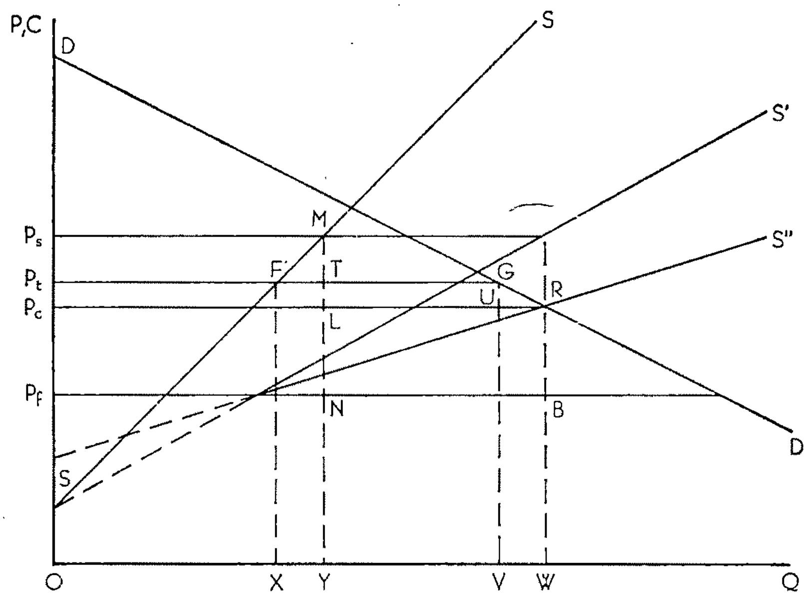

FIGURE 3. A FIXED LEVEL OF IMPORTS

production over total receipts from sale of that output (P_sP_cLM) is equal to the total value of the import licenses distributed ($LNBR$). But in contrast to case (a), in which imports expanded in proportion to domestic production, the increased consumption comes entirely from additional domestic production. This is because imports are fixed. Since consumers are willing to pay less (P_c) for an additional unit of output than it costs to provide (P_s) under the constraint of fixed total imports, the proportionally distributed quota is welfare-inferior to an ordinary tariff/quota in achieving this objective. The result follows because the objective is itself the limitation of trade. A tariff/quota is the optimal instrument in this case, since it equalizes the marginal cost of increased domestic production and reduced domestic consumption. The additional welfare cost incurred by use of a proportionally distributed quota is measured by $FMYX - GRWV = FMT + GRU$.

Policy objective (c), a fixed level of domestic production OX, is well suited to the use of a proportionally distributed quota; in contrast to the previous case, expanded domestic production is the stated objective of the program, rather than an undesired side effect of achieving a different end. The value of the import licenses is thus used to give a direct subsidy to the desired activity. There can be no efficiency loss due to higher domestic production with a proportionally distributed quota as contrasted with a tariff/quota, since production must be the same under either alternative. The increase in domestic consumption which results from the use of a proportionally distributed quota comes entirely from lower-cost foreign sources.

The value of k is chosen so as to result in domestic production of OX. As shown in Figure 4, the use of a proportionally distributed quota to achieve the desired production level results in a new equilibrium at N, with a consumer price of P_c and a net welfare gain of $GNMR$ over the use of a tariff/quota. Again, the excess P_sP_cHF of total domestic costs over sales is exactly equal to $HLMN$, the total value of the import licenses distributed. Changing from a tariff/quota to a proportionally distributed quota moves the economy toward the optimum, which would be achieved through the use of a direct production subsidy of $P_s - P_f$ per unit, with free trade.

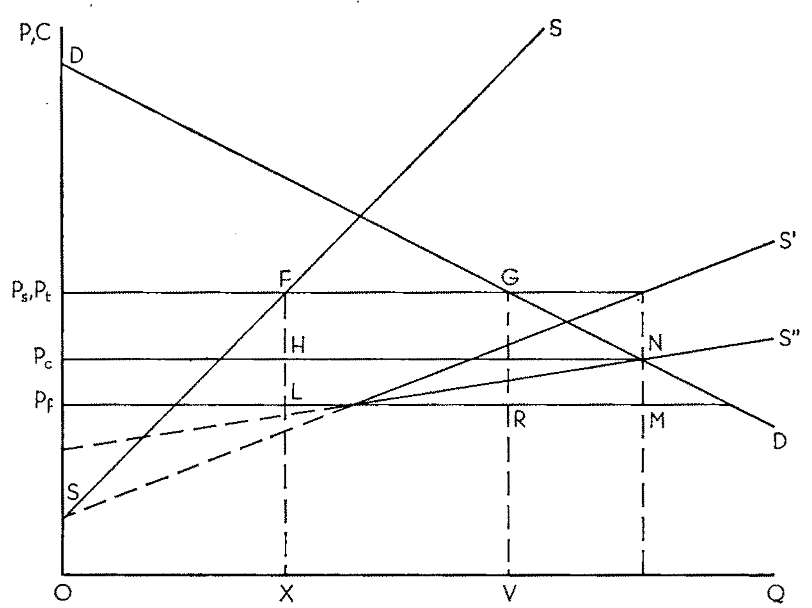

FIGURE 4. A FIXED LEVEL OF DOMESTIC PRODUCTION

For policy objective (d), restricting consumption to OV, the best instrument is a consumption tax. By analogy with the previous case, it is clear that the policy can be carried out more efficiently by a tariff/quota than by a proportionally distributed quota, since the former provides a higher consumption tax for a given level of production subsidy. The welfare loss from using a tariff instead of a consumption tax results from the implied subsidy to production, in this case an undesired subsidy. The additional subsidy produced by a proportionally distributed quota increases this welfare loss.

The analysis so far has assumed that the market supply and demand relationships reflect true social costs and benefits. Where a domestic distortion exists, the correct policy is first to eliminate the distortion through an appropriate tax or subsidy and *then* to apply the instrument indicated by the underlying policy objective. However, this may not always be possible, for the same types of reasons which lead to use of trade restriction where another instrument, such as a direct subsidy, would be more efficient. In such cases, the existence of the distortion may create a stronger presumption in favor of one of the policy alternatives available. For example, if the supply curve overstates social cost, or the demand curve understates social benefit, there is a stronger argument for employing a proportionally distributed quota rather than an equivalent (in achieving the policy objective) tariff/quota.

Similarly, where optimum tariff possibilities are present, the correct policy is first to impose the optimum tariff, and then to use the appropriate form of trade restriction as indicated by the relevant policy objective.

We may summarize the argument as follows: In comparison to a tariff or equivalent quota, a proportionally distributed quota produces an *additional* subsidy to production and a *reduced* tax on consumption. Under competitive conditions, import restriction policies carried out through a proportionally distributed quota rather than a conventional tariff/quota will be more efficient to the extent that the additional production and consumption thus induced tend to contribute to the underlying objective of the policy. If markets are competitive, the import licenses may be given to producers or to consumers without affecting the result, so long as a proportional distribution is employed.

Where the underlying objective of trade restriction is to maintain a desired ratio of

imports to domestic production, a proportionally distributed quota is the optimum instrument to achieve that objective. In addition, the proportionally distributed quota is a *practical* means of implementing the objective, since it can be put into effect without first estimating the supply and demand relations, and does not require revision when changes in these relations occur.[10] However, where a tariff or auctioned quota is replaced by a proportionally distributed quota, the government revenue thus lost must be replaced through another tax.

[10] The cost of pursuing the policy does, however, depend upon the supply and demand relations.

Effective Protection and Decreasing Returns to Scale

By EITAN BERGLAS AND ASSAF RAZIN*

The concept of effective protection was first developed in the context of a Leontief input-output economy. Only recently has the concept been defined and applied to any constant-returns economy.[1] Jones and Mayer have analyzed effective protection in a general equilibrium model with two commodities. They have shown that effective protection, through its effects on the prices of primary factors, will not necessarily increase the output of the protected industry.[2]

In this paper, we analyze the effects of changes in effective protection in a partial equilibrium context. The partial equilibrium approach to effective protection requires decreasing returns to scale. Otherwise, any increase in effective protection holding primary factor prices constant will result in an indefinite increase in output.[3] The analysis of effective protection in industries with decreasing returns to scale has been carried out mainly for the case of fixed imported-input coefficients.[4] The following analysis does not impose any restriction on the form of the production function. Elsewhere we have analyzed effective protection in a general equilibrium model with more goods than factors. The partial equilibrium analysis to be developed in this paper is preserved unchanged in our general equilibrium model.[5]

Jones' definition of effective protection holds for any constant returns to scale production function. We develop a method by which any decreasing returns production function can be transformed into a constant returns production function by an addition of a fictitious factor of production. Using this transformation, the extension of Jones' definition of effective protection to any decreasing returns production function is straightforward.[6]

In this paper we shall show that in the case of decreasing returns to scale, in a partial equilibrium context, effective protection may *decrease* the output of the protected industry. For this case to arise, there is no need to assume any extreme biases in substitution among factors of production. It is demonstrated that a decrease in production is possible even in the case where the production function is weakly separable between the imported input and primary factors.[7] Since output may decline as a result of effective protection with decreasing returns to scale under fairly general situations, it seems that the case no longer deserves to be regarded as a paradox.

Mordechai Kreinin, James Ramsey, and Jan Kmenta have recently analyzed effective protection in the context of decreasing returns to scale. However, their analysis is

* Department of economics and the Foerder Institute, Tel-Aviv University. We should like to thank Elisha Pazner for helpful comments on an earlier draft. All remaining errors are, of course, our own responsibility. Partial financial support from the Peretz Naftali Fund is acknowledged.

[1] See Ronald Jones. For a similar analysis, see Wolfgang Mayer.

[2] V. K. Ramaswami and T. M. Srinivasan first produced an example of this paradoxical result.

[3] One seemingly exception to this statement is the case in which an industry is producing under constant returns to scale, but some of the factors are specific to the industry and their quantities are fixed. It will become clear in the following analysis that this case is equivalent to the case of decreasing returns to scale analyzed in this paper.

[4] See, for example, Harry Johnson, ch. 14.

[5] See Berglas and Razin. Johnson, ch. 15, has analyzed a similar general equilibrium model, and concluded his analysis with the statement: "It may be that the prevailing mixture of general and partial analysis is the most reasonable approach for practical economists interested in commercial questions" (p. 383). The following analysis is, therefore, in the spirit of Johnson's conclusion.

[6] This method, which is demonstrated to be useful in adapting available analysis for constant returns to scale to decreasing returns to scale in the case of effective protection, may prove to be useful in other cases.

[7] The case of a separable production function is widely used by William Corden in the analysis of effective protection. Within his model Jones shows that even in the separable case protection may lead to a fall in production. We show that the same result may happen in partial equilibrium analysis and provide the necessary condition for this possibility.

restricted to the case of *CES* production function with one imported good and one variable primary factor. In our paper, by introducing the fictitious factor of production, the analysis of effective protection is not restricted to any specific functional form of the production function, nor to one imported intermediate good and one variable primary factor. In their paper, Kreinin et. al. failed to distinguish between changes in value-added and changes in the price of value-added. In our paper, we introduce this distinction; we also show (contrary to their result which is based on a nontraditional definition of effective protection), that changes in effective protection, defined as changes in the price of value-added, are always *proportional* to changes in the rent.

I. Effective Protection for a Decreasing Returns Production Function

In this section, we use Jones' definition of effective protection—which was developed in the context of constant returns to scale—and apply it to a decreasing-returns-to-scale production function.

Let $X=F(K, L, M)$ be a decreasing-returns-to-scale production function of commodity X in its three factors of production: capital (K), labor (L), and an imported intermediate good (M). This production function can then be transformed into a constant-returns-to-scale production function by adding a fictitious factor T as follows:

$$(1) \qquad X = G(K, L, M, T)$$

where G is linear homogeneous in K, L, M, and T. For convenience choose $T=1$. Define G as

$$(2) \quad G(K, L, M, T) = TF\left(\frac{K}{T}, \frac{L}{T}, \frac{M}{T}\right)$$

It can be easily checked that if we multiply K, L, M, and T by $\lambda>0$, output will be multiplied by λ. Since $T=1$, it is obvious that $F(K, L, M)=G(K, L, M, T)$ so that the addition of the factor T does not change the production relation between output X and the factors K, L, and M. Let the prices of X, K, L, and M be denoted by P, R, W, and P_M, respectively. If all prices are given, the output and the quantities of the factors are determined. Denote the resulting rent by P_T. It is obvious that if the industry is faced with the same given prices P, R, W, P_M, and P_T, and the industry is restricted to the use of one unit of T, the same output and quantities of factors will result.

Using this transformation, it is straightforward to apply the definitions of value-added and its price introduced by Jones to a decreasing-returns-to-scale production function. We now define the value-added per unit of output as follows:

$$(3) \qquad a_L W + a_K R + a_T P_T = a_v P_v$$

$$(4) \qquad a_v P_v + a_M P_M = P$$

where a_i is the input-output coefficient of factor $i (i=L, K, T, M)$, a_v is the input-output coefficient of the value-added, and P_v is its price. Following Jones' analysis, the change in P_v (which is the change in effective protection rate) is given by:[8]

$$(5) \qquad \hat{P}_v = \frac{\hat{P} - \theta_M \hat{P}_M}{1 - \theta_M}$$

where $\hat{X}$ denotes dX/X and θ_i is the distributive share of input i.

Substituting equation (3) into (4), differentiating while holding W and R constant, and using the cost minimization property for linear homogeneous production function

$$\theta_L \hat{a}_L + \theta_K \hat{a}_K + \theta_M \hat{a}_M + \theta_T \hat{a}_T = 0$$

we get

$$(6) \qquad \hat{P}_T = (\hat{P} - \theta_M \hat{P}_M)/\theta_T$$

Furthermore, rewriting (6) using equation (5), we get

$$(6') \qquad \hat{P}_T = ((1 - \theta_M)/\theta_T)\hat{P}_v$$

[8] This is equation (A.6′) in Jones. It must be emphasized that this equation is valid for the general case of N primary factors and S imported factors—provided we redefine

$$\theta_M = \sum_{i \in S} \theta_{Mi} \quad \text{and} \quad \hat{P}_M = \sum_{i \in S} \frac{\theta_{Mi}}{\theta_M} \hat{P}_{Mi}$$

where θ_{M_i} and P_{M_i} are the distributive share and the price of imported factor i, respectively. Hereafter θ_M and $\hat{P}_M$ will represent the composite intermediate good.

Thus, the rent always changes in the same direction as effective protection. Clearly,[9] the rate of increase in the rent exceeds the rate of increase of P_v. This result resembles Mayer's conclusion that effective protection has a magnified effect on relative factor rewards.

II. Output Effect of Effective Protection

In order to analyze the output effects, it is necessary to specify in greater detail the characteristics of the fictitious production function.[10] Given fixed W and R, the input-output coefficients are functions of the rent and the price of the imported intermediate input.

$$(7) \quad a_i = a_i(P_T, P_M) \qquad i = K, L, T, M$$

Since $T=1$ we have

$$(8) \quad a_T X = 1$$

Differentiating (8)

$$(9) \quad \hat{X} = -\hat{a}_T(P_T, P_M)$$

Denoting $E_i=(\partial a_T/\partial P_i)(P_i/a_T)$, equation (9) can be rewritten as

$$(10) \quad \hat{X} = -[E_T\hat{P}_T + E_M\hat{P}_M]$$

Substituting equation (6′) into (10) we get

$$(11) \quad \hat{X} = -\left[\frac{(1-\theta_M)}{\theta_T} E_T\hat{P}_v + E_M\hat{P}_M\right]$$

Although E_T and E_M represent the elasticities of the fictitious input-output coefficient a_T, they necessarily have the familiar sign characteristics, namely, $E_T<0$ and $E_M \gtreqless 0$, depending on whether the fictitious factor is a substitute or complement for the imported good.

Equation (11) can be presented alternatively in terms of elasticity of substitution.[11]

$$(11') \quad \hat{X} = -[(1-\theta_M)\sigma_{TT}\hat{P}_v + \theta_M\sigma_{TM}\hat{P}_M]$$

It is straightforward to derive from equation (11) two cases known from existing literature: (a) $E_M=0$; this will be the case if the imported intermediate good has a fixed input-output coefficient. (b) $\hat{P}_M=0$; this is the pure case in which effective protection is a result of changes in tariff on the final product only. In these two cases we have the well-known result that effective protection will increase the output of X. However, this result is not generally correct.

We can now derive the necessary and sufficient conditions for an increase in effective protection to result in a smaller output. From equation (11′) we get a necessary condition $\sigma_{TM}\hat{P}_M>0$. Substituting equation (5) into equation (11′), using $\sigma_{TT}<0$, we get the necessary and sufficient conditions for effective protection to result in $\hat{X}<0$ as follows:

$$(11'') \quad \theta_M\hat{P}_M < \hat{P} < \theta_M\hat{P}_M\left(1-\frac{\sigma_{TM}}{\sigma_{TT}}\right)$$

Given inequality (11″), it is necessary to distinguish among three cases:

Case a: $\hat{P}_M>0$ (therefore $\hat{P}>0$): In the case of $\sigma_{TM}>0$ we have $(1-\sigma_{TM}/\sigma_{TT})>1$, therefore inequality (11″) is nonempty.

Case b: $\hat{P}_M<0$, $\hat{P}\geq 0$: The left-hand side of inequality (11″) is redundant. From the right-hand side of the inequality in the case of $\sigma_{TM}<\sigma_{TT}$, we have $(1-\sigma_{TM}/\sigma_{TT})<0$; therefore, the inequality (11″) is nonempty.

Case c: $\hat{P}_M<0$, $\hat{P}<0$: In the case of $\sigma_{TM}<0$ we have $(1-\sigma_{TM}/\sigma_{TT})<1$, therefore inequality (11″) is nonempty.

We have shown that effective protection in the nonempty cases presented in a, b, and c will result in a decrease in output.

The reader may suspect that paradoxical results occur only in the case of inferior inputs.[12] However, this is not true. Inferiority

[9] Note that $1-\theta_M=\theta_T+\theta_L+\theta_K$

[10] Output effects are hereafter analyzed by the use of a production function. On the level of the industry, the analysis can be done in the following way: (a) If all firms are identical, the whole industry can be described by an aggregate production function. (b) If the industry consists of (identical) constant-returns-to-scale firms, but all use a factor which is specific to the industry, the same analysis applies. (c) If the industry consists of nonidentical firms, then the change in output of the industry is the sum of the changes of output of individual firms.

[11] Observe that $E_T=\theta_T\sigma_{TT}$ and $E_M=\theta_M\sigma_{TM}$, where σ_{ij} is the partial elasticity of substitution of i for j, as defined in R. G. D. Allen, p. 504.

[12] See J. R. Hicks, p. 93.

of M is necessary only in Case b. This can be seen most clearly in the case where $\hat{P}=0$. Then we have a decline of output associated with a reduction of the price of P_M which can occur if and only if M is an inferior factor.[13] A fortiori, M is inferior if $\hat{P}>0$, $\hat{P}_M<0$ and $\hat{X}<0$. In Case a; inferiority of the composite input of K and L is implied when $\hat{P}>\hat{P}_M$. Using zero homogeneity in prices of profit maximizing output, this is equivalent to the case in which $\hat{P}_M=0$, $\hat{W}=\hat{R}<0$ and $\hat{P}>0$. Since $\hat{W}=\hat{R}$, factors K and L can be regarded as a composite factor; thus, by the same reasoning as in Case b above, the composite factor must be inferior.

In Case a, when $\hat{P}_M>\hat{P}$, and in Case c, input inferiority is not required. This can perhaps be seen most clearly in Case a, where the rise in marginal cost will exceed the rise in the price of the final product when effective protection is increased, so that output will decline. It must be emphasized that in these cases "paradoxical" results do not require extreme assumptions about substitution between factors of production. We illustrate this result for a decreasing-returns Cobb-Douglas production function.[14]

III. The "Paradox" with a Separable Production Function: An Illustration

Let $X=F(K, L, M)=K^{\alpha_K}L^{\alpha_L}M^{\alpha_M}$ where $\sum_i \alpha_i<1$ and $\alpha_i>0$ $(i=K, L, M)$. Then

$$G(K, L, M, T) = K^{\alpha_K}L^{\alpha_L}M^{\alpha_M}T^{\alpha_T}$$

where $\alpha_T=1-\sum_i \alpha_i$. Under competition, the rent is equal to the marginal productivity of the fictitious factor T:

$$\alpha_T \frac{P}{a_T} = P_T \tag{12}$$

Substituting equations (6) and (12) into equation (8) and differentiating, we get:[15]

$$\hat{X} = \frac{(1-\alpha_T)}{\alpha_T}\hat{P} - \frac{\alpha_M}{\alpha_T}\hat{P}_M \tag{13}$$

The necessary and sufficient condition for $\hat{X}<0$ and $\hat{P}_v>0$ is

$$\frac{1}{\alpha_M} > \frac{\hat{P}_M}{\hat{P}} > \frac{1-\alpha_T}{\alpha_M}$$

$$\text{and} \quad \hat{P}_M > 0$$

Observe that since $\alpha_M<1-\alpha_T$, it is necessary in this case that $\hat{P}_M>\hat{P}$.

IV. Concluding Remarks

We have shown that the standard measure of effective protection is a good predictor of changes in the rent of the decreasing returns industry. However, changes in output are not uniquely related to changes in this measure.[16] Furthermore, increase in effective protection in many cases will lead to a decline in output. Ruling out the possibility of inferior inputs, production will expand whenever the rate of increase in output price is greater than or equal to the rate of increase of imported input price.

[14] The example of the Cobb-Douglas production function, which is weakly separable between M and other inputs, demonstrates that in the case of decreasing returns separability does not insure that effective protection will increase output. It may be recalled that separability was introduced as a sufficient condition for effective protection to result in increased output in the case of constant returns to scale.

[15] The same result can be obtained from equations (5) and (11′) using $\theta_i=\alpha_i(i=K, L, M, T)$ and $\sigma_{TM}=1$ and $\sigma_{TT}=-(1-\alpha_T)/\alpha_T$ for the Cobb-Douglas case. Observe that equation (13) is identical to equation (8) in Kreinin et. al.

External Diseconomies in Competitive Supply: Comment

By George A. Hay and John J. McGowan*

In a recent article in this *Review*, Charles Goetz and James Buchanan (G-B) assert that " . . . the standard description of misallocation in the presence of external production diseconomies is misleading . . . " because these externalities produce a " . . . combination of exchange-inefficiency with production-inefficiency [which] renders the construction of correction devices much more difficult" (p. 889). Stated otherwise their contention is that with external diseconomies that are internal to an industry, i.e., those that each firm in an industry inflicts on other firms in the same industry, a competitive regime in the presence of a per unit tax on output designed to eliminate the difference between private and social marginal cost will not achieve a Pareto optimum. The competitive equilibrium even after the imposition of the corrective tax lies inside the production possibilities frontier.[1]

The purpose of this note is to suggest that the G-B analysis while technically correct is based on a set of assumptions that differs in a particular aspect from what we believe to be the assumptions of the neoclassical paradigm. Moreover within the framework of the neoclassical model we show the standard prescription regarding a corrective tax to be correct. As it turns out, the difference between the G-B model and the neoclassical model is likely to be negligible in any meaningful application but in any case we show that in the G-B model, a lump sum tax imposed on top of the standard Pigovian per-unit tax will restore full Pareto optimality.

G-B assume that the total cost function of any firm has the following specific functional form:

$$(1)\quad c_i = k + q_i^a + Q_i^b q_i \qquad a > 1,\ b > 0$$

where q_i is the firm's own output, Q_i is the aggregate output of all *other* firms in the industry, and where $b>0$ indicates the presence of a technological external diseconomy. All firms are assumed to have the same cost function.

A general version of such a cost function is the following:

$$(2)\qquad c_i = g(T/n, T)$$

where c_i is total costs for firm i, T is total industry output and n is the number of firms in the industry. Since all firms are assumed to have the same cost function, efficiency requires that output be distributed evenly among them. Thus, with n firms, each will produce T/n units.[2]

Dropping the subscript i, we can write total industry costs for any output T as:

$$(3)\qquad TC = nc = ng(T/n, T)$$

The first condition for Pareto optimality is that of production efficiency, i.e., any output T should be produced at minimal

* Associate professors, Yale University. We are grateful to William Brainard, Joseph Stiglitz, and Martin Weitzman for helpful comments.

[1] As G-B point out, the issue involves technical rather than pecuniary externalities since it is well known that the latter cause neither exchange nor production inefficiency. Moreover we assume G-B intended to restrict their analysis to external diseconomies in the production of a final (consumption) good rather than an intermediate good. We think it is clear that the neoclassical writers have recognized that external diseconomies in an intermediate goods industry would cause the unregulated competitive equilibrium to lie inside the economy's production possibilities frontier, since producers of final products would be led to choose inefficient input combinations. However even in this case the neoclassical writers, correctly we believe, would claim that a simple Pigovian tax on the intermediate product in question would restore full Pareto optimality.

[2] Near the end of their paper, G-B generalize their original cost function in the form: $f(T/n,\ T-T/n)$. Obviously, without further restrictions on g or f, the two are indistinguishable. We use (2) because it highlights the key neoclassical assumption more effectively, but the identical result can be obtained using the G-B version.

total cost to society. The policy variable for the "social planner" is T/n, or since T is given, n. Thus we wish to minimize total industry costs with respect to n for a given T. This requires:

$$(4)\quad \frac{\partial TC}{\partial n} = c + n \cdot \left(\frac{\partial c}{\partial T/n}\cdot\frac{\partial T/n}{\partial n} + \frac{\partial c}{\partial T}\cdot\frac{\partial T}{\partial n}\right)$$
$$= c + ng_1(-T/n^2)$$
$$= c - g_1 \cdot T/n = 0$$

where $g_1 = \dfrac{\partial c}{\partial T/n}$

$$(5)\quad \therefore\ g_1 = \frac{c}{T/n}$$

but $c/(T/n)$ is average costs, AC, for each firm. Therefore, efficiency in production requires that production take place in each firm up to the point where $g_1 = AC$.

The second condition for Pareto optimality is efficiency in exchange. This in turn requires that total industry output be expanded to the point where price is equal to social marginal cost. The latter is defined by:

$$(6)\quad \frac{\partial TC}{\partial T} = n\left(\frac{\partial c}{\partial T/n}\cdot\frac{\partial T/n}{\partial T} + \frac{\partial c}{\partial T}\right)$$
$$= n\left(\frac{g_1}{n} + g_2\right)$$
$$= g_1 + ng_2$$

where $g_2 = \dfrac{\partial c}{\partial T}$

Thus the condition for exchange efficiency reduces to:

$$(7)\quad P = g_1 + ng_2$$

On the other hand, profit maximization for the firm requires that production be expanded to the point where price equals *private* marginal cost, MC. The latter is defined by:

$$(8)\quad MC = \frac{\partial c}{\partial q_i} = \frac{\partial c}{\partial T/n} + \frac{\partial c}{\partial T}\cdot\frac{\partial T}{\partial q_i}$$
$$= g_1 + g_2\frac{\partial T}{\partial q_i}$$
$$= g_1 + g_2 \left(\text{since } \frac{\partial T}{\partial q_i} = 1\right)$$

where we have used the q_i term to indicate that the marginal cost for any one firm producing T/n is defined in terms of increasing only its own output, with all other firms continuing to produce at T/n.[3]

We assert that a key assumption of the neoclassical paradigm is that firms regard any increase in costs caused by the diseconomy effect of higher industry output as an exogenous *shift* in their cost curves, unrelated to changes in their own or industry output.[4] This is equivalent to the assumption that firms perceive g_2 as equal to zero.[5]

If this assumption about firms' perception of g_2 is correct, the first condition for Pareto optimality will be fulfilled, since competitive equilibrium will be established where $P = MC = AC$, which reduces to $g_1 = c/(T/n)$ as in (5). (Of course if g_2 is negligibly small, the assumption is unimportant since we see from (8) that equilibrium output and the Pareto optimal output differ by the order of g_2. Moreover as we shall see, there is strong reason to believe that g_2 will be negligibly small in meaningful applications.)

To secure exchange efficiency, the neoclassical economists prescribed a per-unit tax on output. If that tax is set equal to ng_2,

[3] Implicit in (8) is the assumption that the diseconomy effect is a function of total industry output independent of its distribution among firms. This assumption is not critical to the main results. We could have written (1) as $c_i = g(q_i, q_{i+1}, q_{i+2}, \ldots, q_{i+n-1})$. The first-order conditions would be more complex but their nature would not change. The G-B cost function does *not* assume that the diseconomy is independent of the distribution of total output but the nature of the required tax is unaffected by this asymmetry.

[4] John Chipman in an elegant analysis of the neoclassical argument makes this assumption most explicit.

[5] The spirit of this assumption is identical to that under which a firm in perfect competition assumes that expansion of its own output will not affect market price.

we have as a condition for private profit maximization:

$$(9) \quad P - ng_2 = g_1$$

$$\therefore \; P = g_1 + ng_2 \text{ as required by (7)}$$

Thus, under what we believe to be the assumptions of the neoclassical paradigm for external diseconomies, the prescription of a per-unit tax equal to the difference between private marginal cost and social marginal cost is the correct one and is sufficient to restore the economy to a Pareto optimal position.

We note now that where n is large, as we would expect in perfect competition, ng_2 can be significant even though g_2 is negligible. Moreover, *if g_2 is not negligible*, a tax equal to ng_2 would be so large as to probably require a complete shutdown of the industry, or at best an output so small that atomistic competition would not be feasible and a totally different set of controls would be required. Therefore, in any case in which the prescription of a Pigovian tax could be a feasible remedy, there is reason to believe that g_2 would in fact be negligibly small, and the neoclassical assumption would not be unrealistic.

Despite the above, if firms do *not* ignore g_2, then each firm expands production to the point where $P = g_1 + g_2$, and the tax required to restore exchange efficiency is changed to $(n-1)g_2$. In that event, the production efficiency condition will *not* be satisfied since then we will have:

$$(10) \quad P - (n-1)g_2 = g_1 + g_2 = \frac{c}{T/n}$$

thus:

$$(11) \qquad g_1 = \frac{c}{T/n} - g_2$$

violating (5).

This situation can be remedied, however, if we impose in addition to the per-unit tax, a lump sum tax equal to $g_2 \cdot T/n$. Doing so will cause competitive equilibrium to be established where:

$$(12) \; P - (n-1)g_2 = g_1 + g_2 = \frac{c + g_2 \cdot T/n}{T/n}$$

resulting in $g_1 = c/(T/n)$ as required by (5).

Thus if firms regard the level of diseconomy as beyond their control, which we believe is the assumption of the neoclassical paradigm, the Pigovian tax guarantees Pareto optimality. Where firms recognize the relation between industry output and their own costs, the competitive equilibrium with the Pigovian tax lies inside the production possibilities frontier by a factor of the order of g_2 which it seems reasonable to expect will be negligibly small when the number of firms is large. In any case, full Pareto optimality can be restored by a lump sum tax on top of the Pigovian per-unit tax.

Examination of the G-B model reveals that the *only important difference* between it and the neoclassical model is precisely the assumption about g_2. In the G-B model the diseconomy effect of an increase in a firm's output (and therefore total industry output) on its own costs is blended into the cost function along with direct costs and both are assumed to be fully recognized by the firm in deciding how far to expand output.

Thus G-B are correct in asserting that *in their model* the competitive equilibrium, even with the Pigovian tax equal to the difference between private marginal cost and social marginal cost, lies inside the production possibilities curve. What we have shown is that the remaining inefficiency should be negligible. In any case we have also shown that a lump sum tax added to the per-unit tax will be sufficient to restore full Pareto optimality.

External Diseconomies in Competitive Supply: Comment

By ALAN NICHOLS*

Recently in this *Review*, Charles Goetz and James Buchanan advanced the proposition that output-generated external diseconomies may be associated with a production possibilities curve internal to an attainable curve and that under competition it would be the former on which equilibrium would occur. This in turn they take to imply that the conventional tax-bounty analysis offers, in general, an incorrect remedy in that it applies to the wrong production possibilities curve.

The present discussion does not deny that the results indicated by Goetz and Buchanan occur, as they too note, in the context of *input*-generated external diseconomies nor that their results may be conceivable in the context of output generated external diseconomies.[1] We do however deny that the analytical structure they offer in support of their conclusion is admissible.

The analytical case Goetz and Buchanan make is, in terms of Dean Worcester's classification, that of "Externalities which are internal to a specific industry" (p. 884). They employ the crucial specification, on which their results turn, that the costs of each firm (where firms are identical) depend on a function which includes the output of *other* firms, as distinct from total industry output, as an argument. Where c_i, q_i, Q_i are, respectively, firm total cost, firm total output, and output of all other firms corresponding to any particular firm, i, we have

$$c_i = f(q_i, Q_i) \tag{1}$$

For full competitive equilibrium the $mc = ac$ condition requires

$$c_i/q_i = \partial f/\partial q_i \tag{2}$$

Holding industry output, T, constant we have the number of firms, n, as

$$n = T/q_i \tag{3}$$

and

$$Q = (T - q_i) \tag{4}$$

Efficient production, subject to the industry output constraint *and* the particular specification that Q is output only of other firms, requires

$$c_i/q_i = \partial f/\partial q_i - \partial f/\partial Q \tag{5}$$

Thus the output of each firm should exceed that attained under competition or, in other words, for given industry output there should be fewer firms and each should be larger. From this it follows that, since firms are too small, the industry is operating below an attainable production possibilities curve; hence the Goetz and Buchanan conclusions.

To evaluate the Goetz and Buchanan analysis it is necessary first to note that a minuscule change in specification eliminates their conclusions. Thus rewrite (1) as

$$c_i = f(q_i, Q + q_i) \tag{6}$$

and the constraint that T is a constant now produces conventional results, not those they identify. With total industry output the source of external diseconomies we no longer have the curious economies of scale that are implicit in their specification. Since it was the failure to realize these scale economies that presented the interior production possibilities curve in the first place, it is, in turn, not surprising that they find that "... any attempt to impose a per unit corrective tax on the output of firms in the industry will fail" (p. 888). Here their problem is not that of external output diseconomies; it is that the firms are too small. Meanwhile the fact that there are external output diseconomies is a priori neither here nor there for firm size, nor is firm size a priori relevant to external output diseconomies. It is only the "other firm" specification that makes it so.

One might ask is there any advantage in

* Professor of economics, Central Michigan University.

[1] To say that they may be conceivable is not the same as saying that we can conceive of them. See reference in fn. 2, below.

associating external output diseconomies internal to an industry only with output of *other* firms, apart from the advantage of being totally literal? The literature, to our knowledge, discloses no example.[2] The common oil pool case clearly includes the firm's own output summed with the output of other firms. But our failure to conceive of an example need hardly be convincing of the unreality of the case. What may be more convincing are the very curious and quite specific implications of the other firms analysis. As noted, the Goetz and Buchanan firm economies are not ordinary economies of scale. They are not present because a firm is larger. They are not even present because a firm is larger relative to other firms singly considered. They only become present because a firm is larger relative to all other firms together. Formally, where industry output is a variable and where we continue to treat all firms as identical we note that these "economies of scale" would occur whenever the percentage increase in output per firm is less than the percentage decrease in the number of firms. Diseconomies of scale would occur when the inequality is reversed. We find it hard to believe that there is even any point in trying to fill such an economic box.[3]

What is to be said about the introduction of a construct which is unnecessary in explaining the phenomenon with which it deals; which has bizarre and implausible implications; which creates havoc in the analysis of widely accepted policy remedies; and, finally, which is associated with no support other than that which comes from the fact that it has been algebraically specified? We submit that such a construct should be rejected out of hand. What is novel in Goetz and Buchanan, unfortunately, goes with it.

[2] A very convenient survey is in Mark Blaug's discussion.

[3] If Goetz and Buchanan simply wanted to say that, *entirely apart* from output generated external diseconomies, it is possible that firm size might be suboptimal under competition, we would concede that this could be the case and that increases in output need not provide a remedy. But then they would have been saying nothing about output generated external diseconomies, the primary subject of their enquiry. Instead they have slipped in, without comment, a particular algebraic artifice which *definitionally* links firm size and output generated external diseconomies; they do not trouble us with either an empirical or an intuitive linkage. All of this despite the fact the tiniest of changes in their definition eliminates their results altogether.

External Diseconomies in Competitive Supply: Comment

By A. Ross Shepherd*

In a recent article in this *Review*, Charles Goetz and James Buchanan argued that "... familiar descriptions of the nonoptimality properties of competition in the presence of technological external diseconomies are misleading in that they focus exclusively on exchange inefficiency and neglect production inefficiency" (p. 883). With respect to production inefficiency caused by output-generated diseconomies they conclude: "Any fully corrective tax must be more complex than has been realized, since not only marginal cost but also the firm's perception of the *shape* of its average cost curve must be modified" (p. 888). The purposes of this comment are: 1) to reveal the implicit assumption on which this result of Goetz and Buchanan is based; and 2) to show that a more appealing assumption implies the absence under perfect competition of production inefficiency due to output-generated diseconomies.

Goetz and Buchanan (hereafter, G-B) assume an economy comprised of competitive industries. In one industry the (identical) constitutent firms reciprocally impose output-generated technological external diseconomies that are assumed to be "... contained within a well-defined industry category" (p. 883).[1] For each of these firms the total cost function is written (p. 888):

$$c_i = f(q_i, Q_i) \tag{1}$$

where c_i is the total cost of the ith firm, expressed in units of homogeneous input; q_i is the output of the ith firm; and Q_i, the diseconomy argument $(\partial f/\partial Q_i > 0)$, is the total output of all other firms in the industry. According to G-B long-run competitive equilibrium obtains with (p. 888):

$$\frac{c_i}{q_i} = \frac{\partial f}{\partial q_i} \tag{2}$$

That is, with each firm's *ceteris paribus* long-run average cost equal to its *ceteris paribus* long-run marginal cost. Evidently G-B suppose that the competitive firm behaves as if it believed that its output decisions left other firms' outputs unaltered. But this requires that each of the firms ignores repeated observations to the contrary, which is a scientifically unappealing assumption.

The basic reasoning to be applied here was first worked out many years ago by Joan Robinson. The *sine qua non* for a perfectly competitive industry is that each constituent firm faces a demand curve of sufficiently great elasticity that it differs negligibly from a horizontal demand curve. It follows that if the continuous, negatively sloped market demand curve facing the competitive industry is to be taken seriously, as it is in theoretical formulations, it must be assumed that market output is negligibly affected by any one firm's output decisions. And this condition is fulfilled precisely to the extent that an autonomous change in the output of one firm automatically elicits a countervailing *change in the output of the other firms in the industry.*

For any given market demand curve this countervailing reaction is increased as the number of firms increases and the slope of the firms' marginal cost curves decreases. In addition to the ith firm let there be n (identical) firms in the industry. Then:

$$Q_i = \sum_{j=1}^{n} q_j = nq_j \tag{3}$$

If the ith firm changes output, market price (P) changes inversely and the induced change in output by the other n firms will be:

$$\frac{dQ_i}{dP} = n\frac{dq_j}{dP} \tag{4}$$

* Professor of economics, University of Missouri–Kansas City.

[1] This assumption eliminates the possibility of pure exchange inefficiency because all diseconomies (social costs) are internal to the industry and therefore do not distort commodity price ratios away from ratios of social costs.

Evidently the absolute value of this product will increase with the number of firms (n) and the reciprocal of the slope of the marginal cost curves (dq_j/dP). Alternatively put, the greater the number of firms, and the less steep are their marginal cost curves, the greater is the induced countervailing change in output and the less will market price be affected by an autonomous change in output by the ith firm.[2] The perfectly competitive firm, precisely to the extent that it is perfectly competitive, will affect the output of other firms in the industry. Unless we assume that entrepreneurs are obtuse, we must suppose that they will become aware of this reaction, in which case the competitive equilibrium described by G-B is invalid.[3]

If we restate the G-B model without entrepreneurial obtuseness we note:

$$Q_i = Q_i[P(q_i)] \tag{5}$$

Therefore:

$$\frac{dc_i}{dq_i} = \frac{\partial f}{\partial q_i} + \frac{\partial f}{\partial Q_i}\left(\frac{dQ_i}{dP}\,\frac{dP}{dq_i}\right) \tag{6}$$

As the competitive industry approaches perfection the bracketed expression on the right-hand side of (6) approaches -1 and (6) approaches:

$$\frac{dc_i}{dq_i} = \frac{\partial f}{\partial q_i} - \frac{\partial f}{\partial Q_i} \tag{6a}$$

[2] It is perplexing that textbooks fail to explain this fundamental point. The usual textbook formulation should leave readers asking why an increase in output by the competitive firm does not affect price perceptibly whereas that same increment in the same market would supposedly affect price perceptibly if provided by a monopolist.

[3] The competitive equilibrium described by G-B, shown at E^{**} in their Figure 2, p. 886, and at e_i in their Figure 3, p. 887, is unstable. Suppose that all entrepreneurs are obtuse and therefore fail to recognize the connection between the output of one firm and the output of other firms in the industry. Any unplanned change in output of any firm will disturb the competitive equilibrium and market forces will not be generated to restore it. Instead, the market reactions discussed in the text above will work to move the firm along $\bar{ac}$ in G-B's Figure 3.

In the limiting case, then, competitive equilibrium obtains with:

$$\frac{c_i}{q_i} = \frac{\partial f}{\partial q_i} - \frac{\partial f}{\partial Q_i} \tag{7}$$

for each firm, which is the social (production) optimum described by G-B, p. 888.[4] Speaking in terms of G-B's Figure 3, p. 887, each firm located at e_i will see what appears to be the opportunity for profitable expansion. As all firms expand simultaneously market price falls and market quantity demanded increases. The expanding firms reciprocally inflict additional diseconomies, which shift the $\overline{ac}$ and $\overline{mc}$ curves upward. Competitive equilibrium obtains with the now larger firms each producing at minimum unit cost ($\bar{e}'$) with $e_i > \bar{e}' > \bar{e}$. In this situation there is no socially cheaper way to produce the current industry output. Production inefficiency caused by an output-generated external diseconomy is automatically eliminated by the perfectly competitive market.

In sum, if the externality is output-generated economists can continue to use the familiar descriptions of the nonoptimality properties of competition in the presence of technological external diseconomies without being misled, and they can continue to recommend the standard Pigovian corrective without misleading others.[5]

External Diseconomies in Competitive Supply: Reply

By CHARLES J. GOETZ AND JAMES M. BUCHANAN*

The many comments stimulated by our recent paper call into question its concluding assertion that "no real paradigm has existed in this area of the theory of competitive supply." Several critics allege that our conclusions as to the existence of "production inefficiencies as well as exchange inefficiencies" depend on a particular form of the firm's cost function. An alternative form, said to be more in keeping with the standard assumptions of competitive theory, is shown to restore the orthodox analysis in its pristine purity and simplicity, including its implications for the efficacy of Pigovian corrective taxes. While we concede that the critics' specification of the cost function does rescue the orthodox analysis, we dispute whether their formulation more nearly reflects the traditional behavioral assumptions of competitive theory. Indeed, while legitimate argument on the point may exist, we continue to feel that our own formulation embodies the traditional assumptions. In any event, we are unconvinced that the alternative premise should be favored simply because it restores the neatness of the Pigovian prescriptions. The real issue is which of the formulations more accurately captures the behavioral rule followed by competitive decision makers.

I. What is Parametric in Competitive Theory?

We and our critics can probably agree that the essential notion of competition is that all decision makers are "price takers," regarding themselves as unable to affect price by their own quantity adjustments. An alternative expression of this notion is that competitive behavior is *parametric*, taking certain variables as behavioral constants which are part of an exogenously fixed "state of nature." The dispute arises over precisely what variables *in addition to price* are to be included in the set of fixed parameters. We, for instance, include the production of other firms, Q_i, as part of the state of nature faced by the decentralized decision maker, firm i. The opposing school is troubled by one of the logical *lacunae* of competitive theory which arises when we express price as a function of total supply T

$$p = D(T) = D(Q_i + q_i)$$

where the ith firm's own product q_i is allowed to influence T and $\partial p/\partial q_i$ cannot be taken as mathematically equal to zero.

One seemingly appealing way out of the mathematical bind is then to assume, as do our critics, that $\partial T/\partial q_i$ must be zero, that external production adjusts to the ith firm's production q_i in a counterbalancing manner:

$$Q_i = T - q_i$$

In production theory, there is even an apparently plausible rationalization of this assumption since such adjustment may indeed be expected to occur 1) in the long run, and 2) *provided* that the industry also faces constant factor costs.[1] However, the imposition of that latter proviso should suggest to the strict mathematical logician that the price-constancy paradox has merely been swept further under the rug, into input markets.

These difficulties in competitive theory are rendered more emphatic by noting that the analogous problem exists in demand theory. Here, one considers the impact of a single competitive buyer on a good whose supply can, for simplicity, be assumed to be fixed. In the demand model, there is certainly no rationale at all for assuming that other consumers will make exactly counterbalancing adjustments in their bids in order to preserve

* Virginia Polytechnic Institute and State University.

[1] On the assumption of U-shaped average cost curves, a change in the distribution of production among firms will affect the total input requirements for a given output. Changes in factor prices will then be transmitted to firms' cost curve. In general, the original industry output equilibrium would then be disturbed.

price constancy as a single buyer alters his own bids. Mathematically, the single buyer does have an impact on price.

The point of this discussion is that some economists regard the fixity of aggregate supply assumption as a necessary implicit corollary of price-taking behavior. However, as we view it, this fixity assumption is not only not necessary, but does not even fully satisfy the apparent logical demands out of which it purports inexorably to emerge. If the insoluble logical paradoxes presented in the strict mathematical model are regarded in less purist fashion, our interpretation of the competitive assumption as a behavioral rule-of-thumb offers considerable appeal. On this assumption, the competitive decision maker controls only his own personal activity variables and regards all other variables, including output of competitors, as part of a state of nature over which he exercises no control.[2] Our so-called *ceteris paribus* cost functions reflect this conceptualization of competitive behavior, one which is certainly a defensible characterization of the neoclassical competitive model and which we find more descriptive than the suggested alternative.

II. Related Issues

Quite apart from the question of what should be parametric in competitive cost functions, some critics feel that our formulation does not correspond to the traditional notion of industry externalities as being dependent on total industry output rather than on merely the "external" element consisting of other firm's output. There is really no problem here if it is recognized that our assumption about the *single-firm* production function does imply an aggregate *industry* production function in which external costs are determined by total industry output. However, our particular formulation was also specifically aimed at raising an additional question as to whether the behavioral situation of the competitive decision maker does not render the distribution of output among firms inefficient. The neoclassical price theory literature was apparently not concerned with this question and did not precisely define the point at issue here. Hence it would be difficult to adduce evidence from the literature as to which of the alternative formulations was intended. For instance, we fail to see any necessary incompatability between our own model and the standard examples such as the oil pool case.[3] The modern reader should find this ambiguity in the literature unsurprising and judge the alternative conceptions on their own merits.

Our own position would, in any event, attach relatively little empirical importance to what we term the strict "output-generated" externalities customarily discussed under the term "industry diseconomies of scale." Quite clearly, most of the real world examples are input-generated and the simplistic Pigovian output tax is of little practical interest. Our original theoretical argument was developed in the course of a methodological exploration of whether the *average* cost conditions of competitive equilibrium pose any problems within an externalities model. The output-generated case was simply the most straightforward model in which to argue that they do.

Nevertheless, the present argument about the proper specification of behavioral parameters also has implications for the input-generated case. Although we discussed the input-generated case briefly, a more extensive development of essentially the same point was published almost simultaneously by Laurence Schall. Schall's piece does not consider average cost conditions explicitly and leaves the impression that the production inefficiency effect of an externality-generating input may be absent when all firms are identical and the marginal effects are,

[2] Our position seems to be supported by Lester Telser who rejects the price-output constancy definition of competition: "A better definition is that firms act independently. This is the notion given precision by the Cournot-Nash model" (p. 276).

[3] In this case, our model predicts two separate effects. Too much pumping effort will be undertaken and too much oil pumped out of the common pool. In addition, however, there will also tend to be too many separate wells drilled. For any given amount of oil pumped, costs per barrel could be reduced by reducing the number of holes.

consequently, mutually offsetting. Albeit the identical firms assumption is itself a special case, discussions of the competitive model are frequently framed in these terms. What, then, do average cost conditions suggest as a qualification of Schall's conclusion?

If, as our critics allege, competitive firms should properly be conceived of as regarding total industry output as a parameter, then Schall's conclusion requires no qualification. However, if the input-generated case is reformulated analogously to our output-generated case, it can be shown that even identical firms do not achieve production efficiency under the postulated conditions. The nature of the inefficiency cannot, of course, be stated in terms of firm size in this case. Hence, the basic methodological controversy under discussion here does generalize to what may be regarded as more plausible cases of production externalities.

This may also be an appropriate opportunity to make two points which have been the subject of some misunderstanding. Nothing in our analysis suggested that a Pigovian tax could not be used to *improve* resource allocation. Also, although our Figures 2–3 were generated from an explicit production function, and therefore represent conceivable results, we make no claims for the empirical magnitude of the inefficiency effect demonstrated in our theoretical model.

The comment by George Hay and John McGowan does raise a further theoretical issue which touches upon the *magnitude* of the inefficiency implied when the Goetz-Buchanan formulation is employed. This inefficiency depends on the firm's perception of the extent to which its own costs are influenced by changes in industry output, the relevant derivative being denoted as g_2 in the Hay-McGowan terminology. They first argue that g_2 must be negligably small because, otherwise, the appropriate n firm corrective tax of ng_2 would either require a complete shutdown of the industry or permit a number of firms so small that the competitive assumptions would be violated. Then, they point out that the difference between the efficient single-firm solution and the inefficient one varies with the order of g_2. The implication is that the inefficiency noted in our original price is not, in any event, anything to worry about. (A somewhat bizarre result to emerge from defenders of Pigovian orthodoxy.) It seems to us that, on this point, our critics are confused between the *absolute value* of an excess social cost and the *ratio* of the excess social cost to efficient social cost.

Consider a simple example. There are 1000 firms producing whizbangs under conditions of output-generated external diseconomies. Suppose we know that the incremental costs analogous to g_2 for a one-unit increase in industry output T are 1¢. Then the corrective tax is \$10 per unit. In order to believe that g_2 "must" be small, one should be willing to believe that any such industry which pays taxes of \$10 per unit, is either (a) eliminated or (b) reduced to a very small number of firms. Clearly, this argument is not a plausible generalization. As to the percentage cost inefficiency generated, one may well suspect, based on the 1¢ figure, that it is small. However, when industry output T is large, the absolute magnitude of the excess resource cost may nonetheless be very substantial because a small excess cost per unit must be multiplied by the appropriate output figure. In sum, we do not agree that theoretical considerations permit one to assert a priori that the Goetz-Buchanan type of production inefficiency is negligibly small, even though we are similarly unwilling to make the converse assertion that the impact is empirically large.

III. Concluding Remarks

Science advances by attacks on its orthodoxy and there is an important role to be played by the conservative defenders of the faith. If it is not too gross a misplaced metaphor, we would nevertheless suggest that the selection of a behavioral premise on the basis of whether it justifies widely held analytical conclusions is a case of letting the tail wag the dog. Which analysis should be labelled "inadmissible" or "an empty box" depends on how one resolves an ambiguous behavioral aspect of the competitive model. Our concep-

Bond Price Volatility and Term to Maturity: A Generalized Respecification

By MICHAEL H. HOPEWELL AND GEORGE G. KAUFMAN*

One of the more common and accepted generalizations in the mathematics of bond prices is that "... for a given change in yields, the fluctuations in market price will be greater the longer the term to maturity" (W. C. Freund, p. 51). Similar statements may be found in almost every book discussing the mechanics of bond prices.[1] This paper demonstrates that this proposition does not hold in all cases, and we derive the general relationship.

In his important book on the term structure, Burton Malkiel specifies the above relationship between bond prices and maturity as the second of his five general theorems:

> For a given change in yield from the nominal yield, changes in bond prices are greater, the longer the term to maturity. [p. 54]

However, shortly afterwards he notes:

> This theorem is not generally true when yield changes are measured from a base other than the nominal yield. In particular, when bonds are selling at a discount ... it is possible to find cases where longer-term securities are actually less sensitive to a given change in market interest rates than are shorter issues. [p. 55]

Malkiel does not consider this point to have much "practical importance" and does not explore the reasons for its existence. Moreover, it does not prevent him from proceeding to this third theorem:

> The percentage price changes described in Theorem 2 increase at a diminishing rate as N (maturity) increases. [p. 55]

However, the high market rates of interest in recent years have given greater practical importance to the inverse relationship between term to maturity and change in bond price. In a recent book directed at portfolio managers, Sidney Homer and Martin Leibowitz demonstrate this phenomenon numerically for hypothetical bonds. They show that when market interest yields are reduced by 25 percent from 9.5 percent to 7.1 percent, "... 20-year 1's, 2's, 3's, and 4's (coupons) are more volatile than 30-year 9's" (p. 52). The authors find no easy answer for this "puzzling" behavior and conclude that "... the volatility of any conventional high-grade bond results from the interaction of three factors: maturity, coupon, and the starting level of yields" (p. 51).

The apparent inability of analysts to explain this unusual bond price pattern reflects an incomplete understanding of the mathematics of bond prices. While price volatility is related to the time structure of a bond, it is not mathematically related to term to maturity in any simple way. Rather, it is proportionately related to the duration of the bond.[2] The general theorem may be stated:

> *For a given basis point change in market yield, percentage changes in bond prices vary proportionately with duration and are greater, the greater the duration of the bond.*

The validity of this statement for all bonds

* University of Oregon. We are indebted to our colleague, G. O. Bierwag, for helpful comments throughout the development of this paper.

[1] For example, Sergei Dobrovolsky, p. 309; Reuben Kessel, p. 45; Henry Latané and Donald Tuttle, p. 472; Harry Sauvain, pp. 169–73; James Van Horne, p. 76; G. Walter Woodworth, p. 191.

[2] This relationship is implicit in Macaulay's analysis of short- and long-term interest rates but is not rigorously developed. The theorem also lurks in the background in a number of other discussions of bond prices, but, to our best knowledge, has never been stated explicitly. For example, the three elements comprising the definition of duration are all identified by Homer and Leibowitz as affecting bond price volatility but are not put together. Macaulay, pp. 50–51, 61–62; Homer and Leibowitz, pp. 50–53.

is demonstrated below. It will also be demonstrated that this proposition underlies Malkiel's third theorem and that this theorem, like his second theorem, represents a special case that applies only to coupon bonds that sell at or above their par value, and to zero coupon bonds.

Duration is a concept first introduced by Frederick Macaulay to provide more complete summary information about the time structure of a bond than term to maturity.[3] Maturity provides information only about the date of final payment. However, nonzero coupon bonds generate regularly scheduled payments before maturity. Thus, maturity provides an incomplete description of the time pattern of all the payments of a bond. The longer the term to maturity, the higher the coupon rate, or the higher the market yield, the more important are the coupon payments relative to the maturity payment. Duration views a conventional nonzero coupon bond as a zero coupon serial bond with consecutive maturity payments equal to the coupon payments plus a larger payment at final maturity. It thus considers all payments generated by a bond. Duration is defined as:

$$(1) \quad D = \frac{\displaystyle\sum_{t=1}^{n} \frac{(C_t)t}{(1+r_t)^t} + \frac{An}{(1+r_n)^n}}{\displaystyle\sum_{t=1}^{n} \frac{C_t}{(1+r_t)^t} + \frac{A}{(1+r_n)^n}}$$

where

D = Duration
C = Dollar value of coupon payment
A = Dollar value of maturity payment
t = Period in which payment is made
r = Interest rate applicable for period t
n = Maturity period

This formulation is seen to be an ordinary weighted average of the time periods in which payments are to be made. Each period is weighted by the present value of the corresponding payment or price of the maturing serial bond. That is, duration identifies the length of time from the present at which the bond generates the average present value dollar. This period may be considered the average life of the bond. It is equal to the maturity of a single payment zero coupon bond selling at the same market price as the coupon bond, generating the same yield, and having a par value equal to the sum of the total payments generated by the bond when all coupons are reinvested to maturity.

For zero coupon bonds, duration is equal to maturity. For all other bonds, duration is shorter than maturity. However, the relationship between duration and maturity is non-linear and complex. For bonds priced at or above par, duration increases monotonically with maturity but at a decreasing rate. This explains both the much publicized direct relation between price volatility and term to maturity cited earlier and Malkiel's Theorem 3. For discount bonds, the relationship is more complex. Duration increases with maturity to a point before perpetuity, peaks at that point, and subsequently declines.[4] For all bonds, differences between duration and maturity are small for short maturities but increase as maturity increases. Lawrence Fisher and Roman Weil note that for all bonds duration is bounded at perpetuity by $(r+p)/rp$, where r is the yield to maturity and p is the number of times per year inter-

[3] Macaulay, pp. 45–53. A brief history of duration is traced by Fisher and Weil, pp. 415–16. Although not cited by these authors, J. R. Hicks independently of Macaulay appears to have developed the concept of duration, which he refers to as "average period" (p. 186).

[4] For discount bonds, duration achieves its maximum when

$$n = \frac{1}{r} + \frac{1}{r-c} + \frac{r}{r-c} + \frac{r-c}{cr(1+r)^n}$$

where r = interest yield to maturity, c = coupon rate, n = term to maturity, and declines when term to maturity is larger than the value of the right side of the expression. The first three terms of this equation are equivalent to the expression developed by Macaulay as an approximation of the term to maturity at which duration is at a maximum and no longer increases with increases in term to maturity. The complete expression was derived by G. O. Bierwag and may be obtained from the authors on request. As n approaches infinity, the final term approaches zero and Macaulay's approximation is obtained. See Macaulay, p. 50n. The possibility that the duration of discount bonds can be inversely related to maturity appears to have been overlooked by Malkiel, p. 57.

TABLE 1—DURATION OF SELECTED BONDS AT MARKET YIELD OF 6 PERCENT

Years to Maturity	Coupon Rate[a] .02	.04	.06	.08
	Years			
1	0.995	0.990	0.985	0.981
5	4.756	4.558	4.393	4.254
10	8.891	8.169	7.662	7.286
20	14.981	12.980	11.904	11.232
50	19.452	17.129	16.273	15.829
100	17.567	17.232	17.120	17.064
∞	17.167	17.167	17.167	17.167

[a] Coupon payments and compounding semi-annually.
Source: Fisher and Weil, p. 418.

est is paid and compounded (p. 418). For par and premium bonds, this boundary value represents maximum duration; for discount bonds it is less than maximum duration. Examples of the relationship between duration, maturity, market yield, and coupon rate are shown in Table 1 developed by Fisher and Weil. Long-term bonds are seen not to be as long as they may appear.

Duration varies inversely with the coupon interest rate. A 50-year 8 percent coupon bond yielding 6 percent is seen from Table 1 to have approximately the same duration as a 20-year 2 percent coupon bond yielding 6 percent. Fisher and Weil proceed to demonstrate the usefulness of duration in optimizing bond portfolio strategy.

The unique role of duration in relating changes in bond price to changes in interest yields may be derived by computing the differential of bond price with respect to interest rate.[5] The price of a bond (P) is equal to the sum of the present values of the stream of coupon payments and of the final payment at maturity.

$$(2) \qquad P = \sum_{t=1}^{n} \frac{C_t}{(1+r)^t} + \frac{A}{(1+r)^n}$$

Taking the differential:

$$(3) \quad dP = \left[\sum_{t=1}^{n} \frac{-(C_t)t}{(1+r)^{t+1}} - \frac{An}{(1+r)^{n+1}} \right] dr$$

[5] Other properties of duration are described by William Brock and Roman Weil, and Myron Grove.

Factoring $-1/(1+r)$ from both terms in the bracket:

$$(4) \quad dP = -\left[\sum_{t=1}^{n} \frac{(C_t)t}{(1+r)^t} + \frac{An}{(1+r)^n} \right] \frac{dr}{(1+r)}$$

If all coupon payments are discounted by the yield to maturity, the term in brackets is equivalent to the numerator in the definition of duration specified in equation (1). The denominator of equation (1) is equivalent to the definition of bond price specified in equation (2). Substituting from equations (2) and (4) into equation (1) yields:

$$(5) \qquad D = -\frac{dP}{P}\left[\frac{(1+r)}{dr}\right]$$

and solving for dP/P.

$$(6) \qquad \frac{dP}{P} = -D\frac{dr}{(1+r)}$$

For continuous discounting, r approaches 0 and equation (6) reduces to:[6]

$$(7) \qquad \frac{dP}{P} = -D\,dr$$

Equations (6) and (7) confirm the general theorem stated earlier. For a given change in interest rates, percentage changes in bond prices vary proportionately with duration. The maximum change in price occurs when the duration is at a maximum. It follows that the relationship between changes in bond prices and term to maturity depends on the relationship between duration and maturity. If, as maturity increases, duration also increases, the magnitude of the price change increases although at a declining rate. If, as maturity increases, duration decreases, the magnitude of price changes also declines.[7]

[6] These solutions were derived in a different context by Fisher, pp. 113–14.

[7] For example, in his appendix to ch. 3, Malkiel considers a series of hypothetical 2 percent coupon bonds with maturities ranging from one year to perpetuity. He observes that when the market yield is increased from 5.40 to 5.50 percent, the maximum percentage decline in price occurs for a bond with 50 years to maturity. From equation (1), this is also computed to be the approximate maturity of the bond possessing the maximum duration. Both duration and the magnitude

As the relationship between maturity and duration is complex, the relationship between maturity and bond price volatility is also complex.

The linear mathematical dependency of bond prices on duration and not on maturity has a number of important practical implications for the analysis of interest rate behavior. For example, it may be more useful to derive yield curves with respect to duration than to maturity.[8] In recent years, this would show longer maturity Treasury securities to have approximately similar average lives but greatly different before-or after-tax yields. Likewise, it may be necessary to reconsider the contents of the information obtained from forward rates conventionally calculated from yield curves derived from observed coupon securities. It is unlikely that a rate computed for two coupon bonds of different maturities but similar durations indicates the rate an investor would pay now for a forward security commencing at the maturity of the shorter security and maturing at the maturity of the longer security. This may help to explain the limited success of empirical tests in differentiating among competing theories of the term structure.

Lastly, the use of maturity rather than of duration to compare securities may affect the empirical measurements of both liquidity and default risk premiums. The higher interest rates are, the shorter is duration. Thus, the absolute difference in duration between a given pair of short- and long-term bonds will be greater when interest rates are low than when rates are high. As a result, the finding that in a symmetrical cycle yields on long-term securities exceed yields on short-term securities when yields are low by more than short-term yields exceed long-term yields when yields are high may in part or in total reflect the failure to maintain constant the difference in duration.[9] This measurement error may also help explain the inverse relationship between liquidity premiums and the level of interest rates reported by some investigators.[10]

The inverse relationship between duration and coupon makes a higher coupon bond a shorter term bond than a lower coupon bond of the same maturity. To the extent bonds possessing higher risks of default carry higher coupons than default free bonds, a comparison of the rates on these two bonds of equal maturity will underestimate the magnitude of the default risk premium in periods of upward sloping yield curves and overestimate the premium in periods of downward sloping yield curves.[11]

The End of the North-South Wage Differential: Comment

By MARK L. LADENSON*

In a recent issue of this *Review*, Philip Coelho and Moheb Ghali have argued that various studies purporting to show a persistent differential between wages in northern and southern states have used data unadjusted for regional differences in price level; that the differential has been proved for nominal wages, not real wages. Using data for 1963 they show that the average nominal wage rate for a sample of five northern metropolitan areas is significantly greater than such an average for five "southern" metropolitan areas. However, after the nominal wage figures are adjusted for differences in the cost of living in each of the ten areas, this differential disappears. This result survives the introduction of dummy variables to account for differences in industry composition, sex, color, and capital-labor ratio.

It seems almost unbelievable that earlier studies of the wage differential have ignored regional differences in price levels, and Coelho and Ghali must be commended for calling attention to this anomaly. However, they have not proved the end of the North-South wage differential; at least not to the satisfaction of this writer. The reason is that of the five cities used in their southern sample, only one, Atlanta, would be accepted by many as southern, the classification of Baltimore, Dallas, Houston, and Washington, D.C. as southern by the Departments of Labor and Commerce notwithstanding.[1] The purpose of this note is to repeat Coelho and Ghali's comparisons for another sample of cities, half of whose members would be recognized as southern by any reasonable observer.[2] Required data for each metropolitan area are number of production workers, total man-hours, and total wages for production workers, classified by industry, and cost of living indices. The first three items are provided in the *Census of Manufactures 1967* and the latter can be obtained for the year 1967 from the *Handbook of Labor Statistics 1970*.

Table 1 shows that our sample seems to give roughly the same results as that of Coelho and Ghali. Average hourly nominal wages for the five northern areas are 14.4 percent higher than for the southern areas. This differential drops to 4 percent when real hourly wages are considered. The same phenomenon occurs for annual wages. Looking at the figures for the individual cities however, it is clear that Baton Rouge is an extreme outlier. If we compare average hourly wages between the five northern areas and the four southern areas excluding Baton Rouge, we find that when we shift from nominal to real wages the percentage difference drops from 25.6 to 15.1, still a sizeable difference.

It would be preferable to establish the continued existence of the North-South wage differential without excluding Baton Rouge from the sample. This might be accomplished by showing that the high average wages in Baton Rouge are a result of the industrial composition of that region. Our method of distinguishing between regional effects and industry effects is identical to that of Coelho and Ghali. We calculate wage rates and annual wages for every industry (two digit classification) and for every metropolitan area.[3] The model takes the form:

* Assistant professor of economics, Michigan State University.

[1] The title of one of the sessions at the December 1971 meeting of the American Economic Association, at which two papers were presented, was "Is the South Still Backward?" M. I. Foster included only Atlanta in his definition of the South. F. Ray Marshall omitted Baltimore and Washington, D.C. from his definition.

[2] We do not repeat the last part of their analysis involving regional differences in sex, color, and capital-labor ratio.

[3] No observations were available for the following industries in: Boston, SIC 21; Buffalo, SIC 21, 31; Pitts-

TABLE 1—MONEY WAGES, ANNUAL WAGES, REAL WAGES, AND REAL ANNUAL WAGES FOR SELECTED METROPOLITAN AREAS, 1967

Metropolitan Area	Hourly Money Wage	Annual Money Wage	Cost of Living Deflator	Hourly Real Wage	Real Annual Wage
Boston	\$2.94	\$5734.9	106	\$2.77	\$5410.3
Buffalo	3.47	7013.2	103	3.37	6808.9
New York & NE New Jersey	2.86	5569.2	102	2.80	5460.0
Philadelphia	3.07	6051.8	100	3.07	6051.8
Pittsburgh	3.55	6850.3	99	3.59	6919.4
Simple Average (North)	\$3.18	\$6243.9		\$3.12	\$6130.1
Atlanta	\$2.80	\$5670.1	95	\$2.95	\$5968.5
Baton Rouge, La.	3.75	7700.9	91	4.12	8462.5
Durham, N. C.	2.43	4740.5	94	2.58	5043.1
Nashville	2.49	5028.5	93	2.68	5407.0
Orlando, Fla.	2.45	5067.4	92	2.66	5580.4
Simple Average (South)	\$2.78	\$5641.5		\$3.00	\$6092.4
Simple Average (South; Baton Rouge omitted)	\$2.53	\$5126.6		\$2.71	\$5499.8

$$W_{ij} = \alpha + \beta_i + \gamma_j$$

where W_{ij} is the wage in region i and industry j, α is the intercept, β_i is the region effect, and γ_j is the industry effect. The wage W_{ij} is regressed on twenty dummies, the first of which assumes a value of unity for northern metropolitan areas and zero for southern metropolitan areas. The other nineteen dummies each assume a value of unity for one of the twenty industries and zero for every other industry with industry SIC 20 as a base.

It is to be emphasized that observations on Baton Rouge *were* included in the regressions. Looking at Table 2 we see why Baton Rouge is such an extreme outlier. In addition to SIC 20, observations are available for Baton Rouge on SIC 27, 28, 32, 34, implying that these are the major industries in the area. In all four columns of Table 2 the coefficients of these industries are significant and large.

burgh, SIC 21, 22, 24, 31; Atlanta SIC 21, 29, 38; Nashville, SIC 21, 29, 31, 33, 38; Orlando, SIC 21, 22, 26, 29, 30, 31, 33, 37, 38, 39. Observations were available only for the following industries in Baton Rouge, SIC 20, 27, 28, 32, 34; Durham, SIC 20, 22, 27, 32, 36. Instead of 200 observations (20 industries in each of 10 cities) we therefore have 145.

Turning to the coefficient of the North-South dummy we find these also to be large and significant in the first two columns. The fifty-five cent differential between northern and southern nominal hourly wages implies that these are 24.2 percent lower in the South than over the entire sample. The \$991.70 differential between northern and southern nominal annual wages implies that these are 21.2 percent lower in the South than in the sample taken as a whole. These differences are reduced but by no means vanish when we consider real wages. The thirty-two cent North-South difference in hourly real wages means these are 13.1 percent higher in the North than in the entire sample. The \$529 difference in annual real wages means these are 10.6 percent higher in the North than in the entire sample.

Our conclusion is as stated in the second paragraph. Coelho and Ghali have done a service by calling attention to the necessity of using data on *real* wages when considering regional wage differentials. However, the use of such data indicate that the North-South wage differential still exists (or existed in 1967) when the cities used for southern observations in the sample belong unambiguously in that category.

The End of the North-South Wage Differential: Reply

By PHILIP R. P. COELHO AND MOHEB A. GHALI*

In his comment, Mark Ladenson contends that substantial differences in wages still exist between the North and the South even after accounting for differences in regional prices. We find his results objectionable on three grounds: a) his arbitrary exclusion of available data, b) his choice of a low budget cost of living as a deflator, and c) the possibility of heteroscedasticity which would render his testing procedure invalid.

Ladenson objects to four of the five cities we used as our southern sample, all previous empirical work notwithstanding. These five cities were used in our analysis because they were the only five cities for which the necessary 1963 data were available. Similarly, the five cities included in our Northeast sample were the only Standard Metropolitan Statistical Areas (*SMSA*) for which complete 1963 data existed.[1] If we consider 1967 data, there are many more *SMSA*s in both regions than are utilized by Ladenson. (Our data sources are identical to Ladenson's: *Census of Manufacturers 1967* and *Handbook of Labor Statistics 1970*.) In this study we use all the data available by: 1) examining wage differentials throughout the entire United States, 2) offering alternative definitions for the Northeast and South, and 3) using different deflators to measure differentials in the regional cost-of-living.

* Assistant professor of economics, Washington State University, and associate professor of economics, University of Hawaii, respectively.

[1] In our original paper (hereafter C-G) the geographical term North was defined to include the New England and Middle Atlantic states, the region defined by the Bureau of the Census as the Northeast. Because we are convinced that a finer use of geographical terms is necessary to avert terminological debates and to avoid confusion in the examination of wage differentials in other parts of the country, we have modified our regional definition. In this paper unless explicitly stated otherwise, we accept the Bureau of the Census' definitions for the four major regions of the country (Northeast, North Central, South, and West).

The statistical techniques used are similar to those employed by Ladenson and in our previous paper, p. 934, except that we have added two additional dummy variables to account for the additional geographical regions, the North Central and western regions of the United States. Dummy variables, then, exist for the South, North Central, and West of the United States; consequently we are comparing wages in these regions to wages in the Northeast.[2] Industry 21 of the Standard Industrial Classification

[2] The cities for which two-digit industrial classification and comparative cost-of-living data exist are the following:

Northeast Region:
Boston, Mass., Buffalo, N. Y., Hartford, Conn., Lancaster, Pa., New York City and northeastern New Jersey, Philadelphia, Pa., Pittsburgh, Pa., Portland, Me.,

Southern Region:
Atlanta, Ga., Austin, Texas, Baltimore, Md., Baton Rouge, La., Dallas, Texas, Durham, N. C., Houston, Texas, Nashville, Tenn., Orlando, Fla., Washington, D.C.

North Central Region:
Cedar Rapids, Ia., Champaign-Urbana, Ill., Chicago-Northwestern Indiana, Cincinnati (Ohio, Kentucky, Indiana), Cleveland, Ohio, Dayton, Ohio, Detroit, Mich., Green Bay, Wis., Indianapolis, Ind., Kansas City, Mo., Milwaukee, Wis., Minneapolis-St. Paul, Minn., St. Louis, Mo., Wichita, Kan.,

Western Region:
Bakersfield, Ca., Denver, Col., Honolulu, Hawaii, Los Angeles-Long Beach, Ca., San Diego, Ca., San Francisco-Oakland, Ca., Seattle-Everett, Wash.

Ladenson stresses that Baton Rouge, a high wage city, is included in his regression results for the South. Baton Rouge is a high wage city because of its industrial mix, as he points out. Consequently, including Baton Rouge, and using the econometric techniques which both Ladenson and we use, can have no effect upon the southern coefficient unless wages in the Baton Rouge industrial mix are different from wages in the Northeast for the same industrial mix. Ladenson's point is specious.

t-values are in italics below the coefficients.
Starred entries indicate that the coefficients are significantly different from zero at the .05 level.

Code (SIC) is dropped for lack of sufficient data; industry 20 of the SIC serves as a base.

Our results are reported in Table 1. Only regional coefficients are reported.[3] Sample I includes all the *SMSA*s for which 1967 data are available. Sample II excludes the four southern cities to which Ladenson objects and Austin, Texas. Sample III has the same coverage as Sample II except that two northeastern *SMSA*s, Pittsburgh and Buffalo, are excluded. For each sample we report the results for hourly wages (w) and annual earnings (e). The results for money wages

[3] The results of the entire set of regressions are available from the authors upon request.

and earnings are reported in the first five rows. The remaining rows report the results for real wage and real earnings when three alternative deflators are used: Low, Intermediate, and High Budget cost-of-living indexes.

For money wages Ladenson finds that, after accounting for industry mix, annual wages in his "South" are 17.5 percent below the Northeast.[4] In a recent study of interstate wage differentials Gerald Scully found that money wages in the South (Census Bureau definition) were 11.6 percent below those in the Northeast, p. 768. In our original study, p. 934, we found annual wages in money terms in the South to be 10.5 percent below those in the North, hourly wages were 12.4 percent below those in the North. In the present study, in Sample I, the South is 10.7 percent and 11.7 percent below the North for annual money wages and hourly earnings respectively. Whose definition of the South should be accepted?

First, it appears that there should be no dispute over our inclusion in the Northeast of Hartford, Connecticut, Portland, Maine, and Lancaster, Pennsylvania. Complete data for these cities are available for 1967, Ladenson did not use them. Secondly, if Ladenson's results are accepted, one must conclude that between 1958 and 1967 the position of southern industrial workers deteriorated relative to their northeastern counterparts. All the evidence available, quantitative and subjective, belies this conclusion.

In Sample I, for real wages and real earnings the coefficients of the South are insignificant at the 5 percent level except when the data are deflated by the low budget index. We are faced with another problem, which index should we use? Quite obviously, the high budget index is inappropriate for most industrial workers' families.[5] The choice between the low and intermediate indexes is not so clear cut. The annual dollar earnings of each worker would maintain a low budget standard of living. However, there is more than one worker per family; in 1967 50.3 percent of all families in the United States had two family members in the labor force. Furthermore, our data are obtained by dividing the total annual wages paid by the total labor force. No allowance is made for overtime, or part-time and seasonal workers. We believe that the intermediate budget deflator is subject to less criticisms than the alternatives, consequently our conclusions about the difference in wages between the Northeast and South are based upon the use of this index.[6]

In Sample II we drop the cities in areas which Ladenson believes are nonsouthern. However, we use all the northeastern data which are available. The differences between our results and Ladenson's are instructive; in annual money wages and hourly earnings Ladenson has the South 17.5 percent and 19.5 percent below the Northeast, respectively. Our results for the identical variables have the South 14.1 percent and 15.7 percent below the Northeast. Simply by excluding three cities from the Northeast, the differential is widened. Here lies the danger of arbitrarily discarding data.

Ladenson does not give any rationale for rejecting the Census Bureau's definition of the South. By redefining the South, Ladenson's work is not comparable to other studies of the South; consequently, his conclusions are suspect because his data base is different and severely limited. Ladenson's definition of the South has imposed severe limitations upon his sample, resulting in both regional and industrial composition imbalances. Out of his sample of 145 observations only about one-third represent observations on southern industries (52 observations). The imbalance in the distribution of industries may be the

[4] Ladenson states that southern wages "... are 24.2 percent lower in the South than over the entire sample." He actually means that with his data the North is 24.2 percent higher than the South. The South is his base, we have changed his results to a northeastern base to make them comparable with our present and previous findings.

[5] The average annual dollar cost for maintaining a higher-income standard of living for the United States in 1967 was $13,367. This statistic (and others in this section) were obtained from the *Handbook of Labor Statistics, 1970.*

[6] Ladenson uses a low budget deflator although he never mentions it. This is another area of disagreement between us.

cause of his unusually high differentials in nominal wages. If one considers the sign of the industry effects reported in Ladenson's Table 2, seven missing observations for the northern sample are all low wage industries; on the other hand, 30 out of the 48 missing observations for the southern sample have positive signs.

One of the statistical pitfalls in Ladenson's analysis is the inclusion of industries in his northern sample which have no counterpart in his South. The value of the model used is to separate industry effects from regional effects, and, consequently, adjust the regional wage for industry mix. This objective is not achievable if the industry exists in one region only. Industries which are missing from Ladenson's South are SIC 21, 29, and 38. Two other observations (SIC 31 and 33) have only one observation apiece in the southern sample. For this reason we dropped SIC 21 from the sample in our previous

paper, p. 934, and for the same reason we dropped it from the present analysis. With respect to the two other industries, SIC 29 and 38, which would not be represented in the southern sample if we follow Ladenson's definition as we do in Samples II and III, the decomposition of wages to industry and regional effects is accomplished by including the other two regions of the country, where these industries exist.

Nevertheless, let us accept, for illustration, Ladenson's definition and, again for illustration, define the Northeast as the area north of the Mason-Dixon line and east of the Appalachian Mountains. This definition could be defended in terms of geography, history, and market orientation; it constitutes our Sample III. Except for hourly earnings deflated by the low standard of living index, all the southern coefficients are insignificantly different from zero at the 5 percent level. We do not advocate regional definitions of the South nor of the Northeast as defined in Sample III, we do wish to stress that there can be serious biases when data are arbitrarily discarded from a sample.

The results reported may be biased, and, therefore, misleading on two further counts. First, the results may be subject to a specification bias which results from the omission of pertinent variables (such as sex, color, capital-labor ratio). The omitted variables may be working in the direction of concealing the true wage differential. This possibility was investigated in our earlier paper, p. 936, and the conclusion was that inclusion of the omitted variables did not affect our results. This procedure cannot be followed in the present study because the 1958 data on capital and the 1960 data on sex and color are inappropriate for analyzing 1967 wage data.

The second possibility of bias would result if our estimated variance-covariance matrix is biased. Suppose the wage equation which holds for the individual worker k is $w_{ij}^k=\alpha+\beta_i+\gamma_j+e_{ij}^k$ where i represents the ith industry, j the jth city, α the intercept, β_i the industry effects, and γ_j regional effects. If we make the assumption that the error terms e_{ij}^k are spherical normal, then the error term in the equation pertaining to average industry wage levels will not be homoscedastic:

$$w_{ij} = \frac{1}{n_{ij}} \sum_k w_{ij}^k = \alpha + \beta_i + \gamma_j + \frac{1}{n_{ij}} \sum_k e_{ij}^k$$

where n_{ij} represents the number of workers in the ith industry in the jth city. Under these conditions, estimated standard errors of the regression coefficients will be biased, and the calculated t-statistics will not be distributed t, when the results are obtained by applying ordinary least squares. The application of generalized least squares, where the variance matrix is a diagonal matrix with elements $1/n_{ij}$, consists of weighting the original data by a factor which will correct for heteroscedasticity. In our case, the correction amounts to weighting our data by $\sqrt{n_{ij}}$.

In Table 2 the generalized least square results are shown for each of the three samples. Table 2 shows that, in money terms, wages in the South (both annual and hourly) are insignificantly different from wages in the Northeast.[7] Using generalized least squares and deflating by a cost of living index reveals even more startling results. All the southern coefficients are positive and some of them are significant. It is of interest to point out that the southern coefficients are the only ones which change their signs. The other regional coefficients do become larger and their t-values increase. After we account for heteroscedasticity, the Northeast is the low real-wage region.

In conclusion, the results of our previous paper are confirmed and there exist no significant differences in real wages between the Northeast and the South when the accepted

[7] A straightforward interpretation in dollar magnitudes of the regression coefficients is not possible using the correction described. Thus, we have not reported intercept values, and we caution the reader not to interpret the values in simple dollar terms as can be done in Table 1. Complete regression results are available from the authors upon request.

definition of the South is used and when money wages are deflated by the intermediate cost of living index. There are wage differentials within the United States, however. The North Central and western regions have significantly higher wages than the Northeast. Whether these differentials can be accounted for by some other explanatory variables, or whether they are equalizing differentials for nonpecuniary regional differences or whether the economy was simply in disequilibrium in 1967 are questions which can only be answered by further research.

Estimation of Structure-Profit Relationships: Comment

By JOHN M. VERNON AND MARJORIE B. MCELROY*

Recently, the Federal Trade Commission (*FTC*) has accused breakfast cereal manufacturers of illegal monopolization (1971). A major basis for the charge is the *FTC* belief that high advertising expenditures by the companies create effective entry barriers. One *FTC* study (1969) reached this conclusion after finding that the coefficient of the advertising/sales ratio in a multiple regression equation explaining firm profit rates was positive and significant. Several other of these so-called market structure-performance studies have recently been completed (Marshall Hall and Leonard Weiss, Vernon (1972)). However, in a recent issue of this *Review*, Blake Imel and Peter Helmberger (hereafter, I-H) presented some findings which cast serious doubt upon the validity of these studies. According to their carefully specified profit equation for a diversified firm, the significance of advertising as a barrier to entry depends critically on the size of an unknown parameter termed the "*omega* ratio." For example, for one specification of the profit rate equation, the estimated t-ratios varied from 3.31 to 1.86 to 1.29 as the *omega* ratio ranged from 0.0 to 0.5 to 0.8. Since I-H were unable to estimate this ratio and it is not known a priori, it is important to seek evidence as to its magnitude.

In this paper, after a brief review of the I-H model, we suggest a method for estimating the *omega* ratio. We then present some estimates for a body of data similar to that used by I-H. Our results indicate that the estimated ratio (and hence the significance of the estimated coefficients) is approximately the same for two alternative specifications of the model. More importantly, the estimated advertising coefficients, conditional on our estimated *omega* ratios, are positive and statistically significant. Thus, this note tends to corroborate the hypothesis that advertising serves as an effective barrier to entry.

I. The Imel-Helmberger Model

At the cost of placing severe restrictions on the profit equation of a diversified firm, I-H are able to specify the off-diagonal as well as the diagonal elements of the error variance-covariance matrix. Hence, except for the problem of estimating the *omega* ratio and therefore the variance-covariance matrix, generalized least squares (*GLS*) is the appropriate estimation technique.

For a firm specialized in one market, I-H write the profit rate equation as

$$R_i = a + bE_i + cM_i + u_i \tag{1}$$

where

R_i = the profit rate of the ith firm
M_i = a market-related structural variable, such as the concentration ratio, of the ith firm
E_i = a firm-related variable, such as size, of the ith firm
u_i = the total error term, representing both firm-related and market-related omitted variables

A distinctive feature of their model is the assumption that the error term is composed of two components,

$$u_i = e_i + m_i$$

where e_i is that part of the error term due to the omission of firm-related variables and m_i is that part due to the omission of market-related variables. It is assumed that

$$Eu_i = Em_i = Ee_i = 0$$

and

$$\sigma_u^2 = \sigma_m^2 + \sigma_e^2$$

* Professor and assistant professor of economics, Duke University, respectively. We wish to thank Michael McElroy for valuable criticism, Terry Seaks for research assistance, and Bob Nourse for help in collecting the data. We are also grateful to the Marketing Science Institute for its support of the data collection effort.

I-H construct the profit equation for the ith diversified firm from the simple sum of profits of its divisions. Thus the profit equation of the ith diversified firm consisting of two divisions—the gth division operating in market j and the kth division operating in market h—is given by

$$(2)\quad R_{id} = a + b(D_{ij}M_j + D_{ih}M_h) + c(D_{ij}E_{gj} + D_{ih}E_{kh}) + D_{ij}m_j + D_{ih}m_h + D_{ij}e_{gj} + D_{ih}e_{kh}$$

where

D_{ij} = the share of the diversified firm's total sales accounted for by its sales in the jth market

D_{ih} = the share of the diversified firm's total sales accounted for by its sales in the hth market

Generalized to T markets the structure of the variance-covariance matrix of the error term resulting from this model is of special importance. The ith diagonal element is:

$$(D_{i1}^2 + D_{i2}^2 + \ldots + D_{iT}^2)\sigma_u^2$$

The expression in parenthesis is a Herfindahl measure of product diversification, or H_i. For a firm specialized in one market, $H_i = 1$ and hence σ_u^2 is the variance of the error term. A typical off-diagonal element is simply the covariance term for two firms. For example, if firms i and j have at least one market in common, the element is the sum of the cross-products of D_{ik} for the firms' common markets.

$$\sigma_m^2 \sum_{k=1}^{T} D_{ik}D_{jk}$$

If σ_u^2 is factored out of the variance-covariance matrix, the diagonal elements become the H measures of product diversification for the firms in the sample. The typical off-diagonal element becomes

$$K \sum_{k=1}^{T} D_{ik}D_{jk}$$

where K is the *omega* ratio, $K = \sigma_m^2/\sigma_u^2$. Hence, knowledge of K and D_{ik} is sufficient to compute the entire variance-covariance matrix.

II. Estimation Procedure

Our procedure for estimating the *omega* ratio is a simple adaptation of the two-stage technique described by Marc Nerlove, p. 373. In the first stage we account for the effect of the omitted market variables by treating m_k as parameters, and by estimating them using weighted least squares (WLS). These in turn are used to estimate σ_m^2 and thereby K and the variance-covariance matrix. Our procedure differs from that of Nerlove in that the I-H specification requires weighted dummies as well as weighted least squares. The second stage consists of using the estimated variance-covariance matrix and applying generalized least squares. The remainder of this section will be devoted to a fuller discussion of the first stage.

Generalizing the profit rate equation for the ith diversified firm selling in up to T markets yields:

$$(3)\quad R_{id} = bM_i + cE_i + m_1D_{i1} + \ldots + m_TD_{iT} + v_i$$

where

$$M_i = \sum_{k=1}^{T} D_{ik}M_k, \qquad E_i = \sum_{k=1}^{T} D_{ik}E_{ik},$$

$$v_i = \sum_{k=1}^{T} D_{ik}e_{ik}$$

with

$$Ev_i = 0$$

$$\text{var } v_i = \sigma_e^2 \sum_k D_{ik} = \sigma_e^2 H_i$$

Regarding m_k as parameters to be estimated, equation (3) can be estimated using weighted least squares[1] where the appropriate weights are $1/\sqrt{H_i}$.

[1] In Nerlove's first stage, the role of D_{ik} in equation (3) is played by a zero-one dummy variable. In the context of the I-H model, such zero-one dummies would be appropriate only if firms were specialized in one market in which case the coefficient of a dummy variable (plus the constant) would be the profit rate intercept for that market. However, the profit rate intercept for a diversi-

Applying *WLS* to (3) yields an estimated intercept term $\hat{m}_k$ for each of T markets. Thus our estimator of the variance of the error terms due to omitted market variables is given by

$$\hat{\sigma}_m^2 = \frac{1}{T}\sum_{k=1}^{T}\left(\hat{m}_k - \frac{1}{T}\sum_{k=1}^{T}\hat{m}_k\right)^2$$

The residual variance[2] from *WLS* estimation of (3), unadjusted for degrees of freedom, is used as an estimate of the variance of the error terms due to omitted firm variables, $\hat{\sigma}_e^2$. Hence an estimate of the *omega* ratio is

$$\hat{K} = \hat{\sigma}_m^2/(\hat{\sigma}_m^2 + \hat{\sigma}_e^2)$$

This estimate of the *omega* ratio along with D_{ik} is used to calculate the estimated variance-covariance matrix, thus completing the first stage.

III. Illustration

The sample of firms that we use to illustrate the procedure is described fully in a paper by Vernon and R. E. M. Nourse. Briefly the sample consists of 57 large manufacturing firms engaged in selling food, beer, liquor and wine, tobacco, soaps and detergents, household supplies, and toiletries. The data cover the period 1963–69 and were obtained from the usual trade and governmental sources. Industry variables were constructed at the 4-digit SIC level of aggregation. The variables are defined below.

Dependent

R = the firm's net income divided by shareholders' equity, averaged over the years 1963–68

Independent

D_{ik} = the share of the ith firm's sales sold in market k

DC = a dummy variable that equals unity if the weighted[3] average concentration ratio of the firm's product markets is greater than 50, and zero otherwise (1966 4-firm concentration ratios).

CAS = the 1969 advertising/sales ratio of the firm.

AS = the weighted average industry advertising/sales ratio of the firm's product markets

LS = the reciprocal of the logarithm of 1968 total assets of the firm

We examined regressions for two specifications. In model A, the company advertising/sales ratio, CAS, is used as an independent variable along with a market concentration and a firm size variable; in model B, CAS is replaced by AS, the weighted industry advertising/sales ratio.[4]

We report our estimation results for stage one only summarily. Many variations of the stage one procedure were attempted.[5] In all cases the *omega* ratio estimates for models

fied firm is a linear combination of market intercepts. Therefore, in equation (3) each firm has a weighted dummy variable for each market in which it participates, the weights being the share of firm sales in that market. Because we have 40 markets and only 57 observations, the use of a dummy variable for each market would leave us with too few degrees of freedom. A reasonable compromise seemed to be to aggregate the 40 four-digit markets into 11 three-digit markets. Hence, we used 11 dummy variables rather than 40.

[2] Of course, the residual variance must be adjusted to correct for the weighting procedure.

[3] The weights used are the estimated shares of the firm's total sales in each of the 40 4-digit SIC industries covered.

[4] The two advertising variables would appear to raise some ambiguities with respect to the I-H scheme of classifying all variables as either firm or market related. For example, *AS* might be considered to be a bit of both.

[5] Among the variations that we tried were: *WLS* with the weighted dummies representing markets (the weights were $1/\sqrt{H_i}$), and *CLS* with both weighted and unweighted dummies. Imel has pointed out that *DC* is incorrectly constructed *if* one wishes to test the hypothesis that firms earn higher profits in markets where concentration exceeds 50 percent. Rather than defining the zero-one dummy variable on *CR* (as we have done), one should first define the dummies for each market and then construct the firm's variable (*DW*) as a weighted average of the market dummies. We therefore estimated our regressions substituting *DW* for *DC* and found only slight differences in the results. Given the simple correlation coefficient between *DW* and *DC* of .95, this is not unexpected. We should note, however, that the *DW* variable did tend to yield slightly higher t-values. For example, the *DW* t-value in the regression of the profit rate on *DW*, *AS*, and *CAS* was 1.62 as compared with 1.5 for *DC*.

TABLE 1—MULTIPLE REGRESSION EQUATIONS EXPLAINING FIRM PROFIT RATES USING CLASSICAL LEAST SQUARES (*CLS*) AND USING GENERALIZED LEAST SQUARES (*GLS*) WITH FOUR ALTERNATIVE SPECIFICATIONS OF THE VARIANCE-COVARIANCE MATRIX OF THE ERROR TERM

Estimation Procedure	Assumed Value of $\hat{K}$	Intercept	*DC*	*AS*	*CAS*	*LS*	R^2	Equation Number

GLS	0.8	.145	.011 (.32)	1.091 (2.04)[a]		−.335 (−1.82)	.20	(10)

Note: The numbers in parentheses are *t*-ratios; the number of observations is 57.
[a] Indicates significance at the .025 level for a one-tail *t*-test.

A and *B* lay in the range of 0.173 to 0.247. For example, one set of estimates for model *A* yielded $\hat{\sigma}_m^2 = .0012$, $\hat{\sigma}_e^2 = .0043$, and $\hat{K} = 0.217$. The corresponding estimates for model B were $\hat{\sigma}_m^2 = .0012$, $\hat{\sigma}_e^2 = .0045$, and $\hat{K} = 0.207$. For use in stage two, we selected the following representative values of $\hat{K}$:

	$\hat{K}$ (the *omega* ratio)
Model *A*	0.23
Model *B*	0.21

To permit comparison of our results with those of I-H, we estimated models *A* and *B* using classical least squares (*CLS*) and using *GLS* conditional on the following values of the *omega* ratio: 0.00, 0.23 or 0.21, 0.50, and 0.80. These equations are presented in Table 1.

For every equation the signs of our estimated coefficients agree with a priori expectations. As I-H found, the significance of the concentration ratio and the advertising variables tend to fall as the *omega* ratio increases. Contrary to the I-H findings, the advertising/sales ratio remained significantly positive at a .025 level even when the *omega* ratio was set at 0.80. It is interesting to note that the *GLS* results for $K = 0.00$ (equivalent to *WLS*) and for $K = 0.23$ (or 0.21) are so similar that no qualitatively different conclusions can be drawn.

In *GLS* estimation of the I-H model, *ceteris paribus* the larger the *omega* ratio the

more weight is given to the off-diagonal elements of the variance-covariance matrix. That is, the more important are the omitted market variables relative to the omitted firm variables (i.e., the bigger is K), the more we need to take into account the interdependence among error components for firms selling in the same markets. A large K emphasizes this interdependence at the expense of differences among firms' levels of diversification and conversely. In market structure-performance studies prior to that of I-H, the usual practice was to use weighted least squares (i.e., $K=0$) and to neglect the off-diagonal elements of the variance-covariance matrix altogether. Under the I-H specification, this problem would be misleading if in fact K were large. The evidence we have put forward in this note suggests that although K is not zero, nonetheless it is not large enough to make the *GLS* results very different from those for *WLS*. However, we should emphasize that our results are specific to our sample of data.

A final caveat on the use of the I-H model is in order. In order to use their model, it is necessary to have an unambiguous classification of the independent (and omitted) variables as being either firm-related or market-related. This does not always appear to be possible. We have already noted the doubtful classification of the advertising variables in this respect. Another example is a measure of firm size: the *average* size of firms in a market might be viewed as a market-related variable and deviations from the average as firm-related, or the measure might be viewed solely as a firm-related variable (following I-H).

Finally, we do consider the I-H work to be a useful contribution to the growing literature on market structure-performance studies where observations are on firms rather than industries. If for no other reason, I-H are to be commended for highlighting the rather severe assumption that the profit equation of a diversified firm is a simple *linear* combination of profit equations of the firm's divisions.

Estimation of Structure-Profit Relationships: Reply

By Blake Imel and Peter Helmberger*

Recent work has focused attention on the need for more careful specification of the variance-covariance matrix for the error term in the estimation of structure-profit rate relationships. It has been shown that where profit rate data for individual companies are analyzed, the matrix will likely display both heteroskedasticity and autocorrelation.[1] The *omega* ratio, relevant to autocorrelation, is defined as the ratio of the variance of the error component attributable to the omission of market related variables, σ_m^2, to the total variance of the error term, σ_u^2. This ratio appears in every element of the *omega* matrix, defined as $1/\sigma_u^2$ times the variance-covariance matrix, where two firms in the sample represent the same industry. In their comment, John Vernon and Marjorie McElroy estimate that the *omega* ratio is in the neighborhood of .22 and suggest, subject to the need for analysis of additional samples, that neglecting the problem of autocorrelation has rather negligible effects on parameter estimates. In what follows, we draw attention to possible shortcomings of their analysis and argue that the problem of autocorrelation should not be dismissed on the basis of their findings.

Vernon and McElroy propose adapting a two-stage technique developed by Marc Nerlove to estimate the *omego* ratio. They note that the implementation of this technique would entail including a dummy variable for all 40 markets, save one, represented by the 57 firms in their sample. Arguing that this would severely tax the degrees of freedom, they aggregate the 40 sample markets into 11 SIC three-digit groups and hypothesize a dummy variable for each group. We feel that this procedure is not only inappropriate in light of their objectives but indeed, raises a whole host of new problems.

To see this, consider a sample of specialized firms where profit rates are hypothesized to be a function of variables related to firms, markets, and sectors. The total error could then be broken up into component parts as follows:

$$u_{ijt} = e_{ijt} + m_{jt} + g_t \tag{1}$$

where u_{ijt} equals the total error for the ith firm in the jth market in the tth sector and the components e_{ijt}, m_{jt}, and g_t are attributable to the omission of variables related to firms, markets, and sectors, respectively. In our earlier paper, it was assumed that sector related variables and sector related error do not exist; the t subscripts were not required. On this assumption, Vernon and McElroy have included irrelevant variables—the sector dummies—and excluded relevant variables—the market dummies. (This conclusion is hardly altered by allowing for diversification because the equations for diversified firms are mere aggregates of equations for the component "specialized firms.") Theoretically, the Vernon-McElroy estimates of m_j are biased downward toward zero. Indeed, if there were zero correlation between each sector dummy and excluded relevant variables, the estimates of m_j would not be expected to differ significantly from zero. The estimate of the *omega* ratio is biased downward for two reasons. The estimate of the numerator is biased downward because of the downward bias in the estimates of m_j. The denominator is biased upward due to the omission of the relevant market dummies. Clearly, if assuming g_t is nonexistent is valid, the Vernon-McElroy estimate of the *omega* ratio is open to question.

The other alternative, of course, is that relevant sector variables and sector error may in fact exist. What then? For specialized firms, it can be shown that the covariance of the error terms for the two firms in the

* U. S. Department of Agriculture and University of Wisconsin, Madison, respectively.

[1] See our 1971 article. For a discussion of the implications of error component analysis for aggregative approaches, see Imel, Michael Behr, and Helmberger, pp. 77–84.

same market, and therefore in the same sector equals the variance of m_j, σ_m^2, plus the variance of g_t, σ_g^2. The appropriate element of the *omega* matrix would consist of the *omega* ratio plus the ratio of σ_g^2 to σ_u^2. For two firms in the same sector but in different markets, the appropriate element of the *omega* matrix simply equals the ratio of σ_g^2 to σ_u^2. Because of the many patterns of diversification among markets and/or sectors which are conceptually possible, statistical analysis of the error components becomes very complex if the sample contains diversified firms. Moreover, we have some reservations regarding the operationality of the statistical theorems that can be derived. Instead of estimating one variance ratio in the *omega* matrix, one would need estimates of two variance ratios. Application of the Nerlove technique would apparently involve including sector dummies as well as market dummies. It does not appear to us that Vernon and McElroy could have skirted the problem of insufficient degrees of freedom through postulating a sector error component if indeed that was their intent.

Our third and final concern is that the more-or-less straightforward application of Nerlove's suggested technique for the particular problem at hand may not be completely appropriate. As described by Nerlove the technique involves estimating the off-diagonal parameters of the variance covariance matrix when there are T observations on each of N individuals (markets in this case). The variance among the estimated coefficients of the N dummy variables is taken as an estimate of the variance of the "individual related" terms (market related in this case). In industrial organization research, only by coincidence would each market be represented by the same number of sample firms. This raises some substantive questions about the equal weighting each estimated dummy coefficient would receive in computing the variance via the Nerlove technique. An example might clarify this point.

Consider a representative sample of firms from a hypothetical world where all firms are completely specialized. A regression of profit rates on explanatory variables is estimated with a dummy variable included for each market in the sample. In estimating σ_m^2, Nerlove's technique gives each estimated market related term (dummy coefficient) equal weight. Yet, in the sample variance of m_j across firms, some of the market related terms might well be represented many times relative to others. Equal weighting would appear to be a questionable procedure. It is possible, using equal weights, that the estimated market related variance, σ_m^2, will exceed the total variance of the dependent variable in either the sample or population.[2]

In conclusion, while we are sympathetic to the need for estimates of the *omega* ratios in cross-section studies, we must unfortunately report some dissatisfaction with the estimates presented by Vernon and McElroy for their particular study. Though they are to be commended for calling attention to the possibility of using Nerlove's technique to estimate *omega* ratios, their application of this technique has been found wanting in a number of respects. In our view it would be unacceptable in future regressions on company profit rates to assume that the problem of autocorrelation can be neglected on the basis of the Vernon-McElroy findings.

M. Nerlove, "Further Evidence on the Estimation of Dynamic Economic Relations from a Time Series of Cross Sections," *Econometrica*, Mar. 1971, *39*, 359–82.

[2] Another way of viewing the problem is to observe that giving each $\hat{m}_j$ equal weight in the estimation of $\hat{\sigma}_m^2$ is to compute the variance of m_j across markets only. In a regression on firm data however, the variance of m_j is among firms which might be quite unevenly distributed among markets. The difference is in terms of what one is summing over in the variance expression.

Relative Shares and Elasticities Simplified: Comment

By PAUL A. SAMUELSON*

The taxonomy of changing factor shares in a competitive industry's output, as factor supplies (or prices) shift, has, again, been ably discussed.[1] These results can be included under the following terse exposition.

I

Denote the neoclassical (homogeneous-first-degree, concave) production function as $q=f(x_1, \ldots, x_n)$. Then write $X_i = log_e x_i = ln\ x_i$ and

$$(1)\quad ln\, f(x_1, \ldots, x_n) = ln\, f(e^{X_1}, \ldots, e^{X_n}) = \alpha(X_1, \ldots X_n)$$

The relative share of the ith factor,

$$p_i x_i \Big/ \sum_1^n p_j x_j = \alpha_i$$

is then given by

$$(2)\quad \alpha_i = \partial\alpha(X_1, \ldots, X_n)/\partial X_i = \alpha_i(X_1, \ldots, X_n)$$

where subscripts on a function denote partial differentiation, as in $\partial\alpha/\partial X_i = \alpha_i, \partial^2\alpha/\partial X_i \partial X_j = \alpha_{ij}$, etc.

By definition, total relative shares sum to unity; hence

$$(3)\quad \partial\left(\sum_1^n \alpha_i\right) \Big/ \partial X_j = 0 = \sum_1^n \alpha_{ij}(X_1, \ldots, X_n)$$

Effects on α_i, from a relative change in factor i alone are given simply by the sign of α_{ii}, or equivalently of $\alpha_{ii}/\alpha_i\alpha_i$, and $\alpha_{ii}/\alpha_i(1-\alpha_i)$ (the latter being $1-\sigma_i^{-1} = 1 + [x_i f_{ii}/(1-\alpha_i) f_i]$, the "Samuelson" criterion). Effects on α_i from a sole change in factor j are given by α_{ij} or $\alpha_{ij}/\alpha_i\alpha_j$ (which are closely related to the "partial elasticities" concepts, $ff_{ij}/f_i f_j$, of Hicks, Allen, McFadden, Sato-Koizumi, and many others).

To determine how the share of some subset of factors, say $\alpha_1 + \ldots + \alpha_r$, $r<n$, changes relative to some other subset's, $\alpha_{r+1} + \ldots + \alpha_m$, $m<n$, when some factor x_j alone changes, we need only calculate the sign of

$$(4)\quad \partial\left(ln \sum_1^r \alpha_i - ln \sum_{r+1}^m \alpha_i\right) \Big/ \partial X_j = \left(\sum_1^r \alpha_i\right)^{-1}\left(\sum_1^r \alpha_{ij}\right) - \left(\sum_{r+1}^m \alpha_i\right)^{-1}\left(\sum_{r+1}^m \alpha_{ij}\right)$$

Thus, if $r=2$, $m=3=j$, as in Sato-Koizumi's example of a change in brown labor's supply and the effects of this upon its share relative to that of white and black laborers' combined, (4) becomes $(\alpha_1+\alpha_2)^{-1}(\alpha_{13}+\alpha_{23}) - \alpha_{33}^{-1}\alpha_{33}$. If $m=n=3$, (4) becomes $-\alpha_{33}[(1-\alpha_3)^{-1} + (\alpha_3)^{-1}]$.

II

This completes all there is to say.[2]

Mention, however, should be made of the obvious duality relations that hold for the minimum-unit cost function in terms of factor prices, $c(p_1, \ldots, p_n)$, which is dual to the production function and has all its qualitative properties. Now we work with

$$(5)\quad \alpha[Y_1, \ldots, Y_n] = ln\, c(e^{Y_1}, \ldots, e^{Y_n})$$
$$\alpha^i[Y_1, \ldots, Y_n] = \partial\alpha[Y_1, \ldots, Y_n]/\partial Y_i$$

where now brackets (rather than parentheses) differentiate between factor prices and factor quantities, and superscripts (rather than subscripts) indicate differentiation with

* Institute professor, Massachusetts Institute of Technology. I owe thanks to the National Science Foundation.

[1] See Ryuzo Sato and Tetsunori Koizumi. This gives references to Hicks, Robinson, McFadden, Samuelson, Sato-Koizumi, and others.

[2] I have skipped the Sato-Koizumi discussion of "direct and shadow elasticities," dealing with a change in "x_i/x_j," since, when $n>2$, such Robinsonian changes are ill-defined

respect to factor prices (rather than factor quantities).

Now, if we ask the effects on factor shares of changes in one of many factor prices (instead of factor quantities), all our previous formulas can immediately have their duals written, merely by changing subscripts to superscripts! Thus, instead of α_{ii} we write α^{ii}, etc.[3]

[3] The informed reader can verify the following symmetric relations between the "dual" functions:

$$\alpha[Y_1, \dots, Y_n] + \alpha(X_1, \dots, X_n) \geq 0 \tag{6}$$

for $Y_i = ln(p_i / \sum p_j x_j)$ and with (6)'s equality sign holding if, and only if,

$$\begin{aligned} Y_i &= -X_i + ln\, \alpha_i(X_1, \dots, X_n) \\ X_i &= -Y_i + ln\, \alpha_i[Y_1, \dots, Y_n] \end{aligned} \tag{7}$$

In conclusion, and with no implication of criticizing earlier writers (including myself), this terse exposition may usefully point up the fact that most elasticity discussions are empty of substance: for the most part, whether they are partial elasticities or total elasticities, they merely give names to effects that need to be measured—except for their occasional function of relating some of the different needed measurements to each other.

Relative Shares and Elasticities Simplified: Reply

By RYUZO SATO AND TETSUNORI KOIZUMI*

We are gratified that mention of our paper on "Relative Shares" has been made in the preceding note by Paul Samuelson. Consistent with his past contributions, Samuelson has provided a simplified treatment of the various concepts of elasticity of substitution. We would like to take this occasion to make some further observations.

With regard to Samuelson's statement about the usefulness of the elasticity concepts, first, it is hard to imagine that Samuelson would go so far as to belittle the theoretical contributions of all the studies done in such areas as growth, production functions, and technical progress which have greatly benefited by the use of the elasticity of substitution concept. In these studies the elasticity of substitution concept was not used in a trivial manner. Secondly, and this is more relevant to the type of problems we address, there is the matter of substitutes and complements which is an integral aspect of the multifactor analysis. In problems dealing with multifactor production, dual partial elasticity concepts developed by Allen, Hicks, Sato-Koizumi, etc.[1] serve several useful functions. Besides providing a taxonomy of "effects that need to be measured," these various concepts provide us with alternative frameworks of conceiving of substantive problems.

Although it can be shown that the partial concepts are related to some of the other elasticity concepts and hence need not be glorified by fancy names, there do exist particular problems where it is crucial to understand how the "total" effect is divided into its "component" effects. For example, in the case where we are dealing with derived demand with some factors (subsitutes or complements) limited in supply, it is important to know exactly how the existence of substitutability or complementarity among factors works for or against a particular factor share.

NOTES

EIGHTY-SIXTH ANNUAL MEETING OF THE AMERICAN ECONOMIC ASSOCIATION

New York, New York, December 27–30, 1973

Preliminary Announcement of the Program

Thursday, December 27, 1973

2:00 P.M. EXECUTIVE COMMITTEE MEETING

Friday, December 28, 1973

8:30 A.M. PERSPECTIVES ON TWENTIETH CENTURY ECONOMIC THEORY (Joint Session with the History of Economics Society)
Chairman: ROBERT V. EAGLY, State University of New York, Binghamton
Papers: JOSEPH J. SPENGLER, Duke University and University of North Carolina
Was 1922–72 A Golden Age in the History of Economics?
SIR JOHN HICKS, Oxford University
Capital Controversy: Ancient and Modern
Discussants: CARL G. UHR, University of California, Riverside
ROBERT W. CLOWER, University of California, Los Angeles

8:30 A.M. WHAT SHOULD AMERICA'S HOUSING POLICIES BE?* (Joint Session with the American Finance Association)
Chairman: ANTHONY DOWNS, Real Estate Research Corporation
Papers: JOHN KAIN, Harvard University
What Should America's Housing Policies Be? I
FRANK DE LEEUW, The Urban Institute
What Should America's Housing Policies Be? II
Discussants: JAMES L. SWEENEY, Stanford University
MAHLON R. STRASZHEIM, University of Maryland
BENJAMIN CHINITZ, Brown University

8:30 A.M. THE FLOW OF FUNDS AND INTEREST RATES I: U.S. FINANCIAL MODELS* (Joint Session with the American Finance Association and the American Statistical Association)
Chairman: LAWRENCE S. RITTER, New York University
Papers: JAMES S. DUESENBERRY, Harvard University AND BARRY BOSWORTH, The Brookings Institution*
A Flow-of-Funds Model of the U.S. Financial System
JAMES L. PIERCE AND THOMAS THOMSON, Federal Reserve Board
Short-Term Financial Models at the Federal Reserve Board
Discussants: STEPHEN M. GOLDFELD, Princeton University
ALLAN H. MELTZER, Carnegie-Mellon University
DANIEL H. BRILL, Commercial Credit Company

8:30 A.M. A CRITIQUE OF GRANTS ECONOMICS* (Joint Session with the Association for the Study of the Grants Economy)
Chairman: EVSEY DOMAR, Massachusetts Institute of Technology
Papers: KENNETH E. BOULDING, University of Colorado
Micro-Grants-Economics
MARTIN PFAFF, Wayne State University and University of Augsburg
Macro-Grants-Economics
Discussants: JAMES N. MORGAN, University of Michigan
WARREN SAMUELS, Michigan State University

* Not to appear in the *Papers and Proceedings*

10:30 A.M. THE ECONOMICS OF THE FIRST AMENDMENT
Chairman: LEONARD SILK, The New York Times
Papers: RONALD H. COASE, University of Chicago
The Market for Goods and the Market for Ideas
WILLIAM F. BAXTER, Stanford University Law School
On Regulation, Efficiency, and Diversity in Communications Media
Discussants: ROGER NOLL, The Brookings Institution
BRUCE OWEN, Stanford University
ALICE VANDERMUELEN, University of California, Los Angeles

10:30 A.M. THE CONSEQUENCES OF DEMOGRAPHIC CHANGES FOR ECONOMIC POLICY
Chairman: JOSEPH J. SPENGLER, Duke University
Papers: RONALD G. RIDKER, Resources for the Future
Resource and Amenity Implications of Changes in Population Growth Rates
ALAN SWEEZY AND AARON OWENS, California Institute of Technology
The Impact of Changes in Population Growth on Employment
ALLEN C. KELLEY, Duke University
The Role of Population in Models of Economic Growth
Discussants: ANSLEY J. COALE, Princeton University
JOHN R. MEYER, National Bureau of Economic Research and Yale University

10:30 A.M. ENDOWMENT INCOME, CAPITAL GAINS AND INFLATION ACCOUNTING (Joint Session with the American Finance Association)
Chairman: W. ALLEN WALLIS, University of Rochester
Papers: JAMES TOBIN, Yale University
What is Permanent Endowment Income?
JAMES M. LITVACK, BURTON MALKIEL, AND RICHARD E. QUANDT, Princeton University
A Plan for the Definition of Endowment Income
DONALD A. NICHOLS, University of Wisconsin
The Investment Income Formula of the American Economic Association
Discussants: ROBERT EISNER, Northwestern University
J. PETER WILLIAMSON, Dartmouth College
STANLEY W. BLACK, Vanderbilt University

10:30 A.M. WAGE-PRICE CONTROLS I: TWO YEARS OF WAGE-PRICE CONTROLS: WHAT HAVE WE LEARNED? (Joint Session with the American Statistical Association)
Chairman: GEORGE L. PERRY, The Brookings Institution
Papers: BARRY BOSWORTH, The Brookings Institution
Why Phase III Failed
MARY HAMILTON, Loyola University
Price Controls in 1973
ROBERT LANZILLOTTI AND BLAINE ROBERTS, University of Florida
An Inside View of Controls
J. B. MITCHELL, University of California, Los Angeles, AND ARNOLD WEBER, Carnegie-Mellon University
Wages and the Pay Board
Discussants: PHILIP CAGAN, Columbia University
ROBERT SOLOW, Massachusetts Institute of Technology

10:30 A.M. PRODUCTION AND THE AGGREGATE DEMAND FUNCTION FOR LABOR
Chairman: LAWRENCE R. KLEIN, University of Pennsylvania
Papers: NEIL WALLACE AND THOMAS SARGENT, University of Minnesota and The Federal Reserve Bank of Minneapolis
The Elasticity of Substitution and the Cyclical Behavior of Productivity, Average Earnings, and Labor Share
SHERWIN ROSEN, Harvard University and M. I. NADIRI, National Bureau of Economic Research
A Disequilibrium Model of Demand for Factors of Production
ROSS S. PRESTON, University of Pennsylvania
A System of Industry Disaggregate Labor Requirements Equations in an Input-Output Framework
Discussants: ROBERT HALL, Massachusetts Institute of Technology
MICHAEL D. MCCARTHY, Case Western Reserve University
ANNE CARTER, Brandeis University

12:30 P.M. JOINT LUNCHEON* (With the American Finance Association and the American Statistical Association)
Chairman: WALTER W. HELLER, University of Minnesota
Speaker: GEORGE P. SHULTZ, Secretary of the Treasury

2:00 P.M. MONETARY POLICY AND SECTORAL CREDIT FLOWS
Chairman: JOHN KAREKEN, University of Minnesota
Papers: JAMES S. DUESENBERRY, Harvard University
Analysis of the Issues
ANDREW F. BRIMMER, Federal Reserve Board
Alternative Strategies to Influence Credit Flows
Discussants: CRAIG SWAN, University of Minnesota
JOHN M. CULBERTSON, University of Wisconsin
WILLIAM POOLE, Federal Reserve Bank of Boston

2:00 P.M. WAGE-PRICE CONTROLS II: APPRAISAL OF U.S. WAGE AND PRICE CONTROL PROGRAMS* (Joint Session with the American Statistical Association)
Chairman: MORRIS COHEN, Long Island University
Panelists: ROBERT J. EGGERT, RCA Corporation
A View from Industry
GEORGE W. MCKINNEY, Irving Trust Company
A View from the Financial Sector
FRANK W. SCHIFF, Committee for Economic Development
A View from Washington
ABBA P. LERNER, Queens College, City University of New York
A View from Academe

2:00 P.M. INTERNATIONAL TRADE AND FINANCE I: THE POLITICAL ECONOMY OF MULTINATIONAL ENTERPRISES (Joint Session with the Academy of International Business, the American Finance Association, and the American Statistical Association)
Chairman: TIBOR SCITOVSKY, Stanford University
Papers: GARY C. HUFBAUER, University of New Mexico
Problems and Policies in the International Adjustment Process
GEORGE HILDEBRAND, Cornell University
Problems and Policies Affecting Labor's Interests
RAYMOND VERNON, Harvard University
Problems and Policies Respecting Competition and Monopoly Power
Discussants: C. FRED BERGSTEN, The Brookings Institution
PEGGY MUSGRAVE, Northeastern University
ROBERT B. STOBAUGH, Harvard University
THOMAS HORST, The Brookings Institution
JOHN J. MCGOWAN, Yale University

2:30 P.M. WORLD PREJUDICE AND SEX DISCRIMINATION: Findings of The American Economic Association Committee on the Status of Women in the Economics Profession
Chairman: CAROLINE SHAW BELL, Wellesley College
Committee Members: WALTER ADAMS, Michigan State University
KENNETH J. ARROW, Harvard University
FRANCINE BLAU, Trinity College
MARTHA BLAXALL, National Academy of Sciences
KENNETH BOULDING, University of Colorado
JOHN KENNETH GALBRAITH, Harvard University
COLLETTE MOSER, Michigan State University
BARBARA REAGAN, Southern Methodist University
MYRA STROEBER, Stanford University
PHYLLIS WALLACE, Sloan School, Massachusetts Institute of Technology
Panelists: ELIZABETH CLAYTON, University of Missouri
DAVID GORDON, New School for Social Research
(third to be announced)

* Not to appear in the *Papers and Proceedings*

2:30 P.M. MAJOR ECONOMIC POLICY PROBLEMS OF THE 1970s
Chairman: R. A. GORDON, University of California, Berkeley
Panelists: SAMUEL BOWLES, University of Massachusetts
ROBERT L. HEILBRONER, New School for Social Research
KERMIT GORDON, The Brookings Institution
HENDRIK S. HOUTHAKKER, Harvard University
GEOFFREY H. MOORE, National Bureau of Economic Research

2:30 P.M. THE PROPERTY TAX: PROGRESSIVE OR REGRESSIVE?
Chairman: JOSEPH A. PECHMAN, The Brookings Institution
Papers: HENRY J. AARON, The Brookings Institution
Views on Property Taxation: One
RICHARD A. MUSGRAVE, Harvard University
Views on Property Taxation: Two
Discussants: HARVEY E. BRAZER, University of Michigan
ANN F. FRIEDLAENDER, Boston College
DICK NETZER, New York University
GEORGE E. PETERSON, Urbana Institute
EARL R. ROLPH, University of California, Berkeley

3:00 P.M. THE GREAT SOCIETY VERSUS THE NEW FEDERALISM: AN ECONOMIC PERSPECTIVE
Chairman: Congressman PAUL SARBANES
Papers: CHARLES L. SCHULTZE, The Brookings Institution
Sorting Out the Arguments: An Economist's Criteria
LESTER THUROW, Massachusetts Institute of Technology
Cash Versus In-Kind Transfers: Is Economics Myopic About the Tradeoff?
Discussants: KENNETH J. ARROW, Harvard University
(Others to be announced)

8:00 P.M. RICHARD T. ELY LECTURE
Chairman: WALTER W. HELLER, University of Minnesota
Speaker: ROBERT M. SOLOW, Massachusetts Institute of Technology

Saturday, December 29, 1973

8:30 A.M. ALLOCATING RESOURCES FOR POLICY RESEARCH
Chairman: JAMES N. MORGAN, University of Michigan
Papers: F. THOMAS JUSTER, University of Michigan and Institute for Social Research
How Could Survey Research Be More Useful?
ALICE M. RIVLIN, The Brookings Institution
How Could Experiments Be More Useful?
Discussants: BARBARA R. BERGMANN, University of Maryland
MICHAEL H. MOSKOW, U.S. Department of Housing and Urban Development

8:30 A.M. INTERNATIONAL ENERGY SUPPLY
Chairman: SAM H. SCHURR, Resources for the Future
Papers: M. A. ADELMAN, Massachusetts Institute of Technology
Crude Oil Availability and Price Outside the United States
JAMES W. MCKIE, University of Texas
The Political Economy of International Petroleum
Discussants: RAYMOND F. MIKESELL, University of Oregon
THOMAS R. STAUFFER, Harvard University

8:30 A.M. ECONOMICS IN CHINA: THE PROSPECTS FOR SCIENTIFIC INTERCHANGE* (Joint Session with the Association for Comparative Economic Studies)
Chairman: LLOYD G. REYNOLDS, Yale University
Panelists: CARLOS DIAZ ALEJANDRO, Yale University
JOHN GURLEY, Stanford University
DWIGHT PERKINS, Harvard University

* Not to appear in the *Papers and Proceedings*

8:30 A.M. THE FLOW OF FUNDS AND INTEREST RATES II: FINANCIAL ANALYSIS THROUGH THE FLOW OF FUNDS* (Joint Session with the American Statistical Association and the American Finance Association)
Chairman: ALAN GREENSPAN, Townsend, Greenspan, and Company
Papers: DIMITRI BALATSOS, Manufacturers Hanover Trust Company
Homogenizing the Concepts of Financial Market Analysis
PATRIC HENDERSHOTT, Purdue University
Progress Report on a Macro Model of the Financial System
STEPHEN P. TAYLOR, Federal Reserve Board
State of the Statistical Art in Flow-of-Funds Accounting
Discussant: JAMES MCKEON, Salomon Brothers

8:30 A.M. LEXICOGRAPHIC ORDERING AND ITS APPLICATION* (Joint Session with the Econometric Society)
Chairman: NICHOLAS GEORGESCU-ROEGEN, Vanderbilt University
Papers: RICHARD H. DAY AND STEPHEN M. ROBINSON, University of Wisconsin
Economic Decisions with L** Utility
HOWARD KUNREUTHER, University of Pennsylvania
Protection Against Natural Hazards: A Lexicographic Approach
WILLIAM T. TERRELL, Wichita State University
Lexicographic Choice: Pure and Applied Economic Theory
Discussant: JOHN S. CHIPMAN, University of Minnesota

10:30 A.M. THE FIGHT AGAINST POVERTY: CONFLICTING OBJECTIVES AND ALTERNATIVE STRATEGIES FOR INCOME MAINTENANCE (Joint Session with the Association for the Study of the Grants Economy)
Chairman: ANDREW F. BRIMMER, Federal Reserve Board
Papers: ALAIR TOWNSEND AND ROBERT LERMAN, Joint Economic Committee, U.S. Congress
Conflicting Objectives in Income Maintenance Programs: Is There an Easy Way Out?
ROBERT H. HAVEMAN AND IRWIN GARFINKEL, University of Wisconsin
Earnings Capacity and the Anti-Poverty Effectiveness of Income Maintenance Alternatives
Discussants: WORTH BATEMAN, Urban Institute
J. R. DOMINGUEZ, University of California, Los Angeles
PHYLLIS WALLACE, Massachusetts Institute of Technology
VINCENTE T. XIMENES, former Commissioner, Equal Employment Opportunity Commission

10:30 A.M. THE THEORY OF POLICY (Joint Session with the Econometric Society)
Chairman: BENT HANSEN, University of California, Berkeley
Papers: WALTER P. HELLER AND KARL SHELL, University of Pennsylvania
On the Theory of Optimal Taxation with Costly Administration
THOMAS MUENCH AND NEIL WALLACE, University of Minnesota and the Federal Reserve Bank of Minneapolis
On Finding a Good Stabilization Policy: Models and Methods
Discussants: ANTHONY B. ATKINSON, University of Essex
EDMUND S. PHELPS, Columbia University

10:30 A.M. LESSONS FROM AND FOR THE CURRENT ECONOMIC EXPANSION
Chairman: ARTHUR M. OKUN, The Brookings Institution
Panelists: OTTO ECKSTEIN, Harvard University
WILLIAM J. FELLNER, American Enterprise Institute
PAUL W. MCCRACKEN, University of Michigan
PAUL A. SAMUELSON, Massachusetts Institute of Technology

10:30 A.M. INTERNATIONAL TRADE AND FINANCE II: U.S. COMPETITIVENESS IN WORLD MARKETS* (Joint Session with the American Statistical Association and the American Finance Association)
Chairman: ROBERT G. HAWKINS, New York University
Papers: J. DAVID RICHARDSON, University of Wisconsin
Estimating Demand and Supply Parameters for Imports without Import Prices: Methodology and Empirical Results
HELEN JUNZ AND BARBARA LOWREY, Federal Reserve Board
The Effect of Changes in Economic Activity on the U.S. Trade Balance in the Monitoring System for the Balance-of-Payments Process
RICHARD A. LABARGE, Louisiana State University
Foreign Penetration of the Automobile Market in the United States
Discussant: JAMES F. BURTLE, W. R. Grace & Company

* Not to appear in the *Papers and Proceedings*

10:30 A.M. WOMEN AT WORK: AT HOME AND IN THE MARKET (Joint Session with the American Statistical Association)
Chairman: MARINA V. N. WHITMAN, University of Pittsburgh
Papers: MICHAEL J. BOSKIN, Stanford University
The Effects of Government Taxes and Expenditures on Female Labor
ARLEEN LEIBOWITZ, National Bureau of Economic Research and Brown University
Production Within the Household

ANNOUNCEMENTS

Members with suggestions for the meetings in San Francisco, December 28–30, 1974, are invited to send them to Rendigs Fels, Secretary-Treasurer, American Economic Association, 1313 21st Avenue, South, Nashville, Tennessee 37212. The Secretary-Treasurer will review the suggestions and forward them to the Program Chairman. Papers at sessions sponsored by the American Economic Association are ordinarily invited rather than contributed. To be considered, proposals for this Association must be received by the Secretary-Treasurer no later than February 1, 1974. Economists wishing to give papers on econometrics or economic theory may want to submit them to the Econometric Society, which meets with the Association and annually schedules a number of contributed papers.

As many members of the American Economic Association will be aware, the London School of Economics has recently had the opportunity of purchasing a large adjacent building at modest cost which will greatly increase its library facilities. The library of the School is one of the two or three best collections in the world. It is also a collection that is extensively used by American scholars. The British Government has made a contribution to the effort; Sir John Hicks is contributing his Nobel Prize money; a widespread appeal is being launched among the British public; and, quite properly, American economists are being invited to give—a substantial amount if possible, a small contribution in any case. We would like to join in urging all members of the Association to support this potentially valuable resource of our profession. Contributions are tax deductable if made through the American Friends of LSE, P.O. Box 2033, Princeton, New Jersey 08540. Signed Kenneth J. Arrow and John Kenneth Galbraith.

Nominating Committee of The American Economic Association

In accordance with Section IV, paragraph 2, of the bylaws of the American Economic Association as amended in 1972, President-elect Walter W. Heller has appointed a Nominating Committee for 1974 consisting of James Tobin, Chairman; Allen C. Kelley, George Perry, Roy Radner, Christopher Sims, Alice Vandermeulen, and Charles Z. Wilson. Attention of members is called to the part of the bylaw reading, "In addition to appointees chosen by the President-elect, the Committee shall include any other member of the Association nominated by petition including signatures and addresses of not less than 2 percent of the members of the Association, delivered to the Secretary before December 1. No member of the Association may validly petition for more than one nominee for the Committee. The names of the Committee shall be announced to the membership immediately following its appointment and the membership invited to suggest nominees for the various offices to the Committee."

The Executive Committee of the American Economic Association at its meeting on March 2, 1973 voted to increase dues 5 percent effective January 1, 1974, subject to reconsideration at its meeting December 27, 1973. This action was taken under the provision of the bylaws permitting the Executive Committee to increase dues proportionate to increases in relevant costs and prices.

The Asia Foundation has awarded the American Economic Association a grant to assist graduate students and visiting professors from Asia currently at institutions East of the Mississippi to attend the annual meeting of the Association. The 1973 meeting will be held in New York, New York, December 28–30. Approximately sixteen travel grants up to $150 each will be awarded. Inquiries should be addressed to the American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

On Thursday, May 16, 1974, the economics department of the City College of New York will sponsor an all-day conference on "The Economic Analysis of Public Decision Making and Public Processes." The object of the conference is to stimulate research that is relevant to current public issues and policies. Persons interested in reading papers at the conference are invited to submit them to Professor Robert D. Leiter or Professor Gerald Sirkin, Department of Economics, City College of the City University of New York, Convent and West 138th Street, New York, N.Y. 10031. Papers delivered at the conference are scheduled for publication in the second annual conference volume of the department.

Omicron Delta Epsilon, the International Honor Society in Economics, invites the submission of entries for the sixth year of the Irving Fisher and Frank W. Taussig Award Competitions. The Fisher Award consists of $1,000 and publication as a monograph, to be published by Princeton University Press, or a journal article, to be published in the *American Economic Review*. The Taussig Award consists of $100 and publication in *The American Economist*.

Entries for the Fisher Award should be submitted to the Departmental Selection Committees by January 1, 1974, and entries for the Taussig Award by May 15, 1974. They will be judged by the International Editorial Board and finalists by the Final Selection Board, consisting of Professors William J. Baumol, Frank H. Hahn, Leonid Hurwicz, Wassily W. Leontief, and Egon Neuberger (editor). For more information, write to Egon Neuberger, Editor, Economic Research Bureau, State University of New York, Stony Brook, New York 11790.

At the invitation of the Government of the Republic of Austria, the Sixth International Conference on Input-Output Techniques will be held in Vienna, from April 22 to 26, 1974, at the Hofburg Conference Centre. The conference is sponsored by the United Nations and Harvard and Brandeis Universities. Conference languages will be English, French, and Russian. Registration must be completed no later than December 31, 1973. For further information, write to Sixth International Conference on Input-Output Techniques, Postfach 91, A-1103 Vienna, Austria.

American scholars scheduled to participate in international meetings abroad may, as in the past, receive a travel grant from the American Council of Learned Societies. Under the new procedures adopted by ACLS effective October 1973, the applicant must obtain a standard application form from the appropriate society and return the completed form to the society by the applicable deadline: February 15 (for meetings scheduled June to September), June 15 (for meetings scheduled October to January), or October 15 (for meetings scheduled February to May). Applicants will be carefully screened by the society. ACLS instructions state: "*Awards are* restricted to humanists and to those social scientists and legal scholars who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings concerned with the humanistic aspects of their disciplines." Inquiries should be addressed to Rendigs Fels, Secretary-Treasurer, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

The Afghanistan Studies Association has recently been organized to promote research, cooperation, contact, and mutual support among scholars committed to the study of Afghanistan. The Association is affiliated with the AAS. Its initial objective is to bring interested scholars into effective contact and to stimulate greater participation and support for a largely neglected field. Further information on the Association activities and goals can be obtained from the Executive Committee, Richard S. Newell, Chairman, History Department, University of Northern Iowa, Cedar Falls, Iowa 50613.

Deaths

Emile Despres, Stanford University, Apr. 23, 1973.

Robert M. Lichtenberg, economic analyst, Port Authority of New York and New Jersey, May 28, 1973.

N. Arnold Tolles, professor emeritus, New York School of Industrial and Labor Relations, Cornell University, Apr. 10, 1973.

Paul Wiers, retired Federal Civil Service employee, Mar. 12, 1973.

Retirements

Helen A. Cameron, associate professor of economics, Ohio State University, June 1973.

William J. Fellner, professor of economics, Yale University, June 1973.

Raymond W. Goldsmith, professor of economics, Yale University, June 1973.

Emile Grunberg, department of economics, University of Akron.

A. Stuart Hall, professor, department of economics, University of Nebraska-Lincoln, June 1973.

Thor Hultgren, professor emeritus, department of economics, University of Wisconsin-Milwaukee, May 1973.

Clifford L. James, professor of economics, Ohio State University, June 1973.

Edmund A. Nightingale, professor of economics and transportation, University of Minnesota, June 1972.

Peter F. Palmer, professor emeritus, department of economics, California State University, Long Beach, 1972.

Visiting Foreign Scholars

Christopher I. Higgins, Australian Treasury visiting lecturer, University of Pennsylvania, 1973–74.

James Maycock, economic adviser, Midland Bank, London: visiting scholar, department of banking and finance, University of Georgia, spring quarter 1974.

Promotions

Virote Angkatavanich: professor of economics and finance, Fairleigh Dickinson University, Sept. 1973.

The American Economic Review

ARTICLES

DECEMBER 1973

THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

• Published at George Banta Co., Inc., Menasha, Wisconsin.

• THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, and *Directory* and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

• Membership dues of the Association are $21.00 a year, which includes a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature*. Junior membership at $10.50 per year is available to registered students for a maximum of three years. Subscriptions (libraries, institutions, or firms) are $31.50 a year, and only subscriptions to both publications will be accepted. Single copies of the *Review* and *Journal* are $4.50 each plus a $.50 per order service charge. Orders should be sent to the Secretary's office, Nashville, Tennessee.

• Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, Rendigs Fels, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary by the 1st of the month prior to the month of publication. The Association's publications are mailed second class and are not forwarded by the Post Office.

Frank Knight at 70

Frank Knight as Teacher

By DON PATINKIN*

I shall write of Frank Knight[1] as a teacher—and this is really the viewpoint from which I can best describe him. For I do not feel that I have the necessary expertise in the theory of uncertainty and in capital theory—and certainly not in social philosophy—to provide a critical evaluation of Knight's fundamental contribution to these fields. Nor do I have any basis to write of him as a colleague. On the other hand, my most vivid memories of Knight even today are from the days when he was one of my teachers at the University of Chicago (1941–47). Indeed, I saw him afterwards only a few times. Furthermore, my own work in economics has largely been in fields that were not his major concern, and so I read—or reread—little of his work after my student days.

Thus the picture of Knight that I shall draw here is primarily the one that I remember seeing as a student—through the window on the life of his teacher that is open to a student. It is thus a picture of only one aspect of Frank Knight's life—though obviously an important one. And I am fully aware that—like any picture based on personal impressions and memories—it is one that also reveals something about the viewer.

What is the mark of a great teacher? It is first and foremost the qualities he con-

* Professor of economics, The Hebrew University of Jerusalem. Appropriately enough, the first draft of this memoir was written while serving during the fall of 1972 as Ford Foundation Visiting Research Professor of Economics at the University of Chicago. And though the pages which follow are by their very nature a personal document, I have nevertheless greatly benefited from—and am grateful for—the opportunity afforded by this visit of discussing them with D. Gale Johnson, T. W. Schultz, George Stigler, Roger Weiss, and other people at Chicago who knew Frank Knight well. I am also indebted for helpful comments on earlier drafts to Yoram Ben-Porath, Martin Bronfenbrenner, Clarence Efroymson, Richard Freeman, William Ginzberg, Giora Hanoch, Ephraim Kleiman, Leonardo Leiderman, Akiva Offenbacher, David Marawetz, Jerome Stein, Lester Telser, Menahem Trajtenberg, and Menahem Yaari. In view of the personal nature of this memoir, it is really unnecessary to say that none of these individuals bear responsibility for the description that follows.

I would also like to express my appreciation to George Stigler for making Knight's unpublished papers (which are in his custody) available to me, and to Glen Gilchrist (who has catalogued these papers under Stigler's direction) for guiding me through them and xeroxing requested materials. I wish finally to thank Mark Wang at the University of Chicago and Akiva Offenbacher at the Hebrew University of Jerusalem for their valuable technical assistance, and Kathryn Bates and, especially, Vera Jacobs for patiently and accurately typing this memoir through its various drafts. I am also grateful to the University of Chicago, the Central Research Fund of the Hebrew University, and the Israel Academy of Sciences and Humanities for research grants that made this and other assistance possible.

With regard to articles listed in the reference section, page numbers shown in the text refer to the reprinted version, and not to the original.

[1] Frank Hyneman Knight: born, McLean County, Illinois, November 7, 1885; died, Chicago, Illinois, April 15, 1972. The bare facts of Knight's academic career as given by the 1969 *Handbook of The American Economic Association* are as follows: Ph.B., Milligan College, Tennessee, 1911; B.S., M.A., University of Tennessee, 1913; Ph.D., Cornell University, 1916; instructor of economics, Cornell University, 1916–17, University of Chicago, 1917–19; associate professor and later professor of economics, State University of Iowa, 1919–27; professor of economics, University of Chicago, 1927–45; distinguished service professor of social sciences and philosophy, 1945–52; emeritus after 1952.

A bibliography of Knight's writings for the period 1915–35 appears at the beginning of his *Ethics of Competition* (1935, pp. 11–18). For other details of Knight's life, as well as a general description of his work, see James Buchanan; see also Joseph Dorfman, pp. 467–79, 767–70, *et passim*). On Knight's days as a graduate student at Cornell—and his shift then from studying philosophy to economics—see the description of his renowned teacher there, Alvin Johnson (1960, pp. 227–28, 231). (I am indebted to Edward Shils for this reference.) See also the biographical sketch of Knight that appears elsewhere in this issue.

veys by his very presence in the classroom: his personal integrity and his intellectual curiosity and stimulation; his humility and his breadth of interests.

And it is, secondly, the insights and understanding—the new ways of looking at things—that he transmits to his students. Frequently these insights are original to him; but even when they are not, they reflect his judgment as to what is important in the existing body of knowledge, and hence worthy of emphasis. And it is the mark of a great teacher that the insights he thus passes on to his students do indeed remain important: that they continue to guide their thinking many years later; and that these students in turn consider the insights so important as to wish to pass them on to their own students as well.

In all of these ways Frank Knight was a great teacher.

I am afraid that I did not think so in my first contact with him when I tried sitting in on his course on "Price and Distribution Theory" (Economics 301), the first course in economic theory required of all graduate students. I found myself then quite confused by the middle-aged (he was then in his late 50's), medium-height, plumpish and moustached man who stood at the side of the large elliptical wooden table in one of the seminar rooms on the first floor of the Social Sciences Research Building—leaning on the back of a chair, occasionally puffing on a corn-cob pipe—and rambling on in a high-pitched voice and in a disjointed manner on mysterious issues that certainly cast no light on the newly revealed truth which was then being enthusiastically explicated everywhere—in words, in graphs, as well as in mathematical formulas—of "marginal revenue = marginal cost." And after a few such bewildering experiences, I gave up in despair.

But not for long. The following year I registered for the course, and this time succeeded in taking fairly coherent classnotes. But I must admit that my greatest pleasure and benefit from the course came when, toward the end of my graduate studies, I sat through it once again.

Many factors lie behind this long road to understanding and appreciation. First of all, Knight gave little emphasis in his teaching to those things to which the beginning graduate student is normally attracted—namely the technical aspects of the discipline, and the newer the better. In part this was due to the fact that Knight was just not interested in these aspects—and in part because he took this knowledge for granted and wanted to get at the more fundamental issues that lay behind the assumptions and implications of the analysis. And this was not simply a reflection of the period and of the generation—for my classnotes of Jacob Viner's contemporaneous version of the Economics 301 course show that Viner (in addition to being concerned with the broader issues of analysis and scholarship) gave considerably more emphasis to the technical aspects of the analysis than did Knight. Thus, for example—as might be expected from his famous article on "Cost Curves and Supply Curves" (1931)—Viner provided a fairly detailed presentation of the properties of these curves under the assumptions of imperfect as well as perfect competition, though (as I shall note later) Knight too discussed the theory of imperfect competition.

But this was not the only cause of the beginning graduate student's difficulties with Knight's course. For, quite frankly, Knight was not a good teacher in the sense of systematically introducing and developing a subject. Nor did he make a pedagogic effort to motivate the student to understand the subject in question by explicitly relating it to the general framework of economic analysis. All this, Knight took for granted as being known to the student—

and devoted himself instead to forcing the student to rethink the basic issues of economic theory as he saw them.

Another difficulty with Knight's lectures was that at crucial points they frequently (and unawares to the student) turned into brief and cryptic summaries of views that Knight had developed at length in various of his writings—to which for the most part Knight did not explicitly refer. Thus a brief reference to the invalidity of "productivity ethics" or to "commutative justice *versus* distributive justice" could hardly convey the depth and meaning of Knight's famous essay on "The Ethics of Competition." Nor could passing references to "real-cost versus alternative-cost theories of value" mean much to a student who was not aware of Knight's many writings on this question.

For this reason I remember characterizing Knight's lectures at that time as being like a general-equilibrium system—which could not be solved until the student was familiar with the set of Knight's articles that specified the relationships between the various parts of the lectures, and thus converted their unknowns into knowns. And I still remember my feeling of satisfaction when I began to be able to see the system of equations as a whole—and things began to fall into place.

There is one further bit of background information that I feel is relevant to my picture of Knight. The teachers of economic theory during my student days at Chicago included not only Frank Knight and Jacob Viner, but also Oskar Lange—who was the antithesis of Knight, and not only on political grounds. Where Knight devoted much attention to probing (in his rambling and often obscure manner) into the meaning of the basic definitions and assumptions of the analysis ("perfect competition," "perfect foresight," "wants," "costs," "capital," "equality," and the like), Lange (in his contrastingly clear and systematic manner) was primarily concerned with drawing the logical implications of these assumptions. So where Knight taught economic theory in a loose, "literary," philosophical fashion—and was antipathetic to mathematical economics[2]—Lange was formal, rigorous, complete, and frequently made use of mathematical tools (not to mention his invaluable course in Mathematical Economics). And where Knight was basically not sympathetic to the new developments in economic theory (read: Keynes and Hicks)—and even, I would say, instinctively critical of them—Lange was an early convert as well as an efficient expositor and refiner.[3] Thus Knight and Lange complemented each other in a most wondrous way—thereby increasing the productivity of each of them in the teaching process. From the implicit dialogue that thus took place between these two teachers, we students were the direct beneficiaries.[4]

[2] "The mathematical economists have commonly been mathematicians first and economists afterward, disposed to oversimplify the data and underestimate the divergence between their premises and the facts of life. In consequence they have not been successful in getting their presentation into such a form that it could be understood, and its relation to real problems recognized, by practical economists" (Knight 1923, p. 49).

[3] See Lange's 1938 model of the *General Theory* in his "The Rate of Interest and the Optimum Propensity to Consume" and his use and elaboration of the analytical tools of *Value and Capital* in his *Price Flexibility and Employment* (1945).

[4] Unfortunately, neither side to this dialogue—and even more unfortunately, practically nobody at Chicago at that time—represented the empirical approach to economics in the sense of the statistical analysis of quantitative data. From the death of Henry Schultz in 1938 and until the advent of the Cowles Commission in the mid-1940's (whose major concern at that time was not only the methodology of econometric models, but also the actual construction of such models for the *U.S.* economy), this component of a good education in economics was almost entirely absent from Chicago. It should, however, be noted that empirical economics had not achieved the recognized position it now has in the profession, and was accordingly absent from many (if not most) of the other leading academic centers as well.

I. Knight the Theoretical Economist

What were the main features of this world of Knight's? It was first and foremost ("If you don't learn anything else from me, then learn this . . .") the notion of social organization—and the economic system as a means of fulfilling certain basic functions of any such organization: the system whose exact structure varies from society to society, but which for every one of them must answer the basic questions about what goods and services to produce, how to produce them, how to distribute them among the members of the society, and how to provide for the future of the society. The fruitfulness of this view of economics is well-attested by the fact that it has been adopted by such widely used elementary textbooks as those of Samuelson, Lipsey, and others, as to have become by now a commonplace.[5]

Another basic element of Knight's teaching was the view that the study of man—including economic man—could not proceed within the same deterministic framework as the study of nature. For the behavior of man must also express his freedom of will—to which there is no counterpart in the physical world. Hence "fully determined" or "perfectly rational" human behavior is no behavior at all: for such behavior is entirely mechanistic, leaving no place for free choice on the part of the individual. ("Does the apple falling from the tree act rationally? The question is meaningless—since the apple is subject to mechanical forces.") Indeed, the proper study of human behavior must take into account the possibility of error and the existence of exploratory and game-playing aspects of such behavior. Correspondingly, despite his occasional use of analogies from physics, Knight emphasized that we "cannot transfer the laws of the physical sciences to where human beings are concerned" (Classnotes: Econ. 305, 1945).

In the opening lecture of his theory course in 1942, Knight (according to my classnotes) set out his general approach to the analysis of the economic system:

> The main theme of traditional economics is that the investigation of theoretical problems can be settled by argument, without using inductive argument. Discuss things of common knowledge. Most questions solve themselves if correctly stated. No special technique necessary. The current tendency in the literature is a reaction against this view. Want to use inductive thinking—getting at facts. Also use mathematical techniques—statistics. Point of view of this course is not inductive or deductive in the sense of being beyond reach of any educated person. Simple principles of mathematics to be used. [Classnotes, Econ. 301, 1942]

Our basic readings for the course were from Marshall's *Principles* and Davenport's *Economics of Enterprise*.[6] In the

[5] Knight discussed these basic functions in his 1933 booklet on *The Economic Organization*. This reproduces the four chapters that Knight first published in 1932 in the book of readings that was prepared specially for the famous social science survey course developed during the 1930's at the College of the University of Chicago. In the bibliography of Knight's work that appears in the *Ethics of Competition* (1935c, p. 15) these chapters are described as "an abstract of material mimeographed for private circulation at the University of Iowa during the years 1922–25." (This is apparently the material that has been found among Knight's papers and catalogued under the title "*Economics*, 1920's." In any event, this material does contain an approach to economic analysis in terms of the functions of an economy.) For further details on the dating of this material, see fn. 1 in my paper elsewhere in this *Review*. An early version of the discussion of the functions of an economy is to be found in Knight's doctoral thesis, as revised and published in his classic *Risk, Uncertainty and Profit* (1921a, pp. 54 ff). In connection with Samuelson's approach to economics in terms of these functions, see his reference to Knight in the second edition of *Economics: An Introductory Analysis* (1951, p. 14, fn. 1). See also fn. 8 below.

[6] The other reading materials to which we were referred (according to my 1942 classnotes from Knight's 301 course) were as follows: E. H. Chamberlin, *Monopolistic Competition* (1942) (mentioned, but not clear if assigned as reading); R. F. Harrod, "Doctrines of Imperfect Competition" (1934); J. R. Hicks, *Value and Capital*, ch. 1 (1939); F. H. Knight, *The Economic Or-*

opening lecture just mentioned, Knight referred in the following words to these writers and to what he planned to do in the course:

> Marshall was in many ways an eclectic combining supply and demand sides. He was a conservative and a defender of *laissez-faire*. Davenport was one of the most important and original thinkers.[7] He was a radical in the negative sense. . . . Davenport was a forerunner of Keynes. In certain paragraphs one can't tell whether reading Keynes or not.
>
> Knight is for reading a couple of books and getting conclusions of subject rather than reading literature—what people have said (as Viner does). Knight interested in social applications of economic approach; not interested in associating points of view with writers, or in puzzle solving. The big job of economics is to divest people of prejudices—to have them see the questions as they are. Right now ordinary lay opinion should be forgotten as much as possible [by the students, presumably]. [Classnotes: Econ. 301, 1942]

The primary contrast that Knight drew in his lectures—and in much of his writings over the years—was that between two alternative systems for fulfilling the aforementioned functions: the competitive (capitalist) system and socialism. Most of his classroom analysis (as well as of his writings) was devoted to the competitive market system. Here Knight gave an overview of this system in terms of what he called "the familiar figure of the 'wheel of wealth'," (1933a, pp. 60–61, here reproduced in Figure 1) which has become even more familiar to a modern generation of economists through its use by Paul Samuelson in his introductory textbook.[8] Within the framework of this

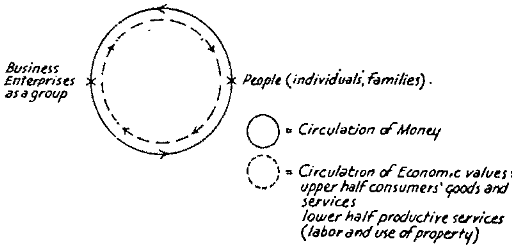

FIGURE 1

ganization (1933a); A. P. Lerner, "Statics and Dynamics in Socialist Economics" (1937). In my 1945 classnotes, there is also a reference to Knight's "The Business Cycle, Interest and Money: A Methodological Approach" (1941).

Other of Knight's writings that we read in connection with this course included: *Ethics of Competition* (1935d), various essays; "The Quantity of Capital and the Rate of Interest" (1936); "Diminishing Returns from Investment" (1944a); and "Realism and Relevance in the Theory of Demand" (1944b). Interestingly enough, there is only one mention in my notes (in the context of a discussion of the nature of profits) of Knight's classic, *Risk, Uncertainty, and Profit*. Nor do I recall our reading this book as students. On the other hand, it is clear in retrospect that many of Knight's classroom discussions stemmed from it.

[7] The deep impact—both intellectual and (I would conjecture) personal—that Davenport had on Knight is most evident from the biographical sketch of him that Knight wrote for the *Encyclopedia of the Social Sciences* (1931). Knight's first contact with Davenport (which—as the foregoing sketch makes clear—also included participation in the latter's classes) apparently took place at Cornell during 1916–17, which was the year that Davenport came to Cornell (Spiegel, 1968, p. 16), and also the year that Knight stayed on there as an instructor after receiving his Ph.D. (see fn. 1, above).

I might also note that the index to Knight's famous "work of his youth," *Risk, Uncertainty, and Profit*, contains more references to Davenport than to any other writer besides J. B. Clark.

[8] Knight's first use of such a diagram can be dated back to 1926 at the latest (see fn. 5 above). Insofar as Samuelson is concerned, see the circular-flow diagrams that appear in all editions of his *Economics: An Introductory Analysis* (e.g., 1948, p. 226; 1970, pp. 42, 170, and 607). I might note that Samuelson did his undergraduate work at the University of Chicago in the early 1930's—and that in reply to my query as to the possible origin of his circular-flow diagram in Knight's teachings, Samuelson has indeed confirmed that "I [Samuelson] was influenced by Knight's elementary (for him) explanation of how the economic system works. In the Social Science Survey Courses I or II, 1932–3 [see fn. 5 above], I am sure I was assigned it to read. And in early editions of my book, I cited Knight for How, What, and For Whom" (personal letter to author dated April 10, 1973, and cited with Samuelson's kind permission). (For his reminiscences of his days at Chicago, see Samuelson (1972a, pp. 158–61; 1972b, p. 5).)

The question of the origins of Knight's diagram itself is an intriguing one that I have discussed at length in a

diagram, Knight then proceeded to explain how the price system (and more specifically, the two sets of prices—those of final goods and services, and those of productive services) "control[s] the process of production and distribution under free enterprise" (1933a, p. 62).

The distinctive elements of Knight's exposition began with his criticism of the term "competition" as a description of the system. This term, emphasized Knight, had a connotation of *personal* competition: whereas the system of perfect competition was an impersonal one. With whom, asked Knight, was the farmer—producing his agricultural output in a perfect market—competing? Thus the use of the term was misleading in failing to bring out that so-called system of *competition* was a system that actually brought about the *cooperation* (though again, in an impersonal manner) of economic units in carrying out the productive processes of the economy. The basic characteristic of this system—and once again Knight prefaced his discussion here (as in many other contexts!) with the injunction "If you don't learn anything else from me, then learn this . . . "—was that the exchanges which take place under this system are to the *mutual advantage* of both parties to the exchange. Indeed, this—according to Knight—was the major innovation of Adam Smith, though one that was frequently not understood even to this day. And he would frequently refer to the levying of tariffs as a flagrant example of the continued failure to understand this fundamental of economic analysis.

In analyzing the productive process, Knight emphasized that it was one in which (like in the usual production function of today) output was essentially simultaneous with input—and he thus criticized the classical model of (agricultural) production as well as the Austrian production-period model of capital theory, both of which presented output as following inputs with a time lag. Knight also emphasized that essentially what was produced (and, even more so, consumed) was not goods, but services—though (he admitted) the distinction tended to vanish in the case of perishable goods which were immediately destroyed in the process of consumption.

In his analysis of production, Knight devoted much attention to an explanation of the proper meaning of the law of diminishing returns. In this context he made the distinction—now to be found in many price-theory textbooks—between the three regions of the total output curve under the assumption of constant returns to scale (see Figure 2): region I, in which the average product of the variable factor, A, is rising; region II, in which both marginal and average product of A are declining; and region III, in which the marginal product of A is negative. Knight went on to emphasize the symmetry between regions I and III that expresses itself in the fact that just as the marginal product of the variable factor A is negative in region III, so must the marginal product of the fixed factor B be negative in region I. Hence, said Knight, in the real world we are always in region II (see 1921a, pp. 97–102).[9]

Within the foregoing framework Knight forcefully expounded an "alternative" or "opportunity cost" theory of value that he contrasted with the classical "real" or

note that appears elsewhere in this *Review*. This also describes the different uses that Samuelson has made of the circular-flow diagram in the various editions of his textbook.

[9] For examples of textbook discussions of Knight's "three regions," see Stigler (1952, p. 115), Ferguson (1969, p. 130), and Grunfeld, Liviatan, and Patinkin (1963, pp. 15–19). Some price-theory textbooks today make use of the assumption of "free disposal" and thus draw the production curve as *Obce* instead of *Oabcd*, or else simply draw only the relevant segment of the curve, *bc*.

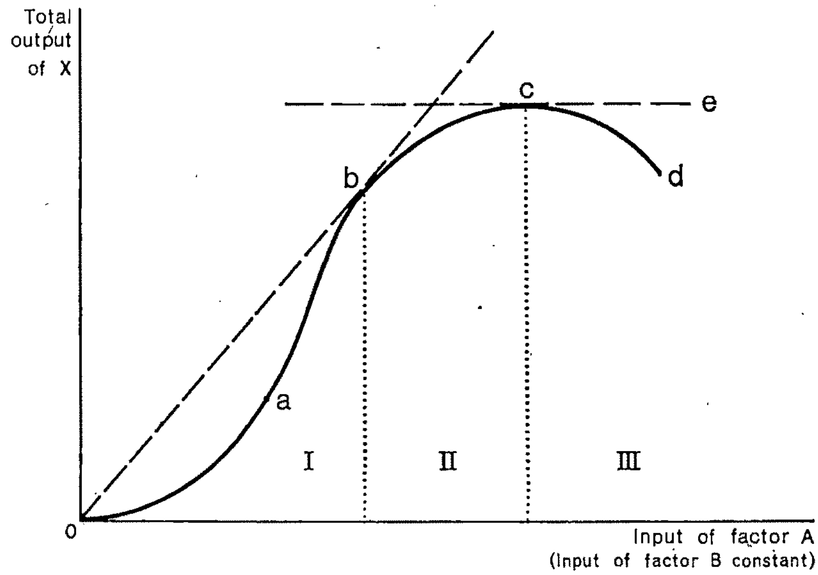

FIGURE 2

"subjective" or "pain cost" theory of value—to the clear disadvantage of the latter. I mentioned before that the beginning student frequently did not understand the issues that Knight was discussing in the classroom until he had found his way to those of Knight's writings that dealt with these issues (and in this case Knight's 1935 article on "The Ricardian Theory of Production and Distribution" was particularly relevant). I might now add that in this case the student's understanding was also advanced in the course of his studies as he became aware (through exposure to Viner's version of the Economics 301 course) that this was not a dead issue, but part of a running debate that Knight was carrying on with Viner. And I must admit that Knight's presentation of the issue in terms of absolute right and wrong (as he was wont to do) was less helpful than Viner's resolution of the debate in terms of including in the individual's calculation of alternatives his subjective tastes for the pains and pleasures he derived from the various labor services he could sell in the market.

In any event, I still find that it deepens one's understanding to follow Knight in emphasizing that Adam Smith's deer was worth two beaver not because of the fact per se that a unit of labor was involved in the catching of each, but because this fact implied that the cost of catching a deer were the two beaver that could alternatively have been caught. Hence (in Knight's terms) the market price for a deer had to be two beaver: for otherwise there would be a discrepancy between what the individual had to forego in order to obtain a (say) deer "directly" (viz., by hunting it) and "indirectly" (viz., by hunting beaver, and exchanging them for the deer), so that market forces of excess supply (or demand) for deer would automatically reestablish the price of two beaver to one deer, should it deviate from this level.

A basic part of Knight's theory course was devoted to the theory of demand, and to the Marshallian demand curve in particular. In this context Knight was less receptive than he might have been to indifference-curve analysis, and there may

indeed be hints of a somewhat more positive attitude to this analysis in his Preface to the 1948 reissue of *Risk, Uncertainty, and Profit* (p. XLVIII). After all, indifference-curve analysis did not challenge anything basic in Knight's general approach, so that I feel that his opposition to it was at least in part a reflection of his reluctance at that time to change traditional modes of thought.

Still, Knight's detailed critique of Hicks' exposition of indifference-curve analysis did provide the student with a deeper understanding of its assumptions. It also enabled Knight to draw a sharp and instructive distinction between the demand curve that Hicks generated by changing the price of the good in question while keeping all other prices and money income constant—so that real income changed along the demand curve; and the Marshallian demand curve, in the generation of which (according to Knight) other prices were changed so as to keep real income constant (1944b, 1946). This interpretation of the Marshallian demand curve was also stressed by Viner in his version of the Economics 301 course (Classnotes, 1944), and so can well be said to be part of a Chicago tradition.[10]

As already noted, Knight discussed (and referred us to the relevant readings on) the theory of monopolistic competition—indeed, to an extent greater than one might infer from some of the things that have been written on the attitude of the Chicago school to this theory.[11] It is, however, true that Knight was critical of Chamberlin's concepts of imperfect competition, and denied that the possibility that an "... enterprise can have a diminishing [i.e., negatively sloped] demand curve but still no monopoly profits ... corresponded to fact" (Classnotes, Econ. 301, 1942).

The most distinctive part of Knight's theory course had to do with his theory of capital—and one cannot but be impressed by the modern flavor of what he taught here. First of all, Knight railed against the traditional classical "trinity of factors of production"—land, labor, and capital. There was little in the productive process that Knight was willing to identify with the "original and indestructible forces of nature" that the classical economists had defined as "land." Agricultural land, too—emphasized Knight—had to be developed and maintained just like any other capital good. Similarly, the productive process of labor reflected primarily not "native qualities," but the artificial qualities which constituted human culture. Thus there is no basic distinction between most of the income received by labor and that received by capital. In the terminology of the more recent "Chicago school" associated with the names of T. W. Schultz, Gary Becker, and others (and I suspect that Knight had some direct or indirect influence on their thinking, too), Knight viewed most of labor income as returns to "human capital" and stressed the role of the family (both genetically and socially) in endowing its children with this capital. Thus Knight was not very far from classifying all of the factors of production under the one general title "capital."

In his more formal treatment of capital theory, Knight—like J. B. Clark before him (1899)—emphasized the basic distinction between specific capital goods in the concrete—which are periodically worn out and reproduced, and the stock of capital in the abstract—which is permanent, and which with the exception of a few historical periods (for example, periods of prolonged warfare) has been continuously

[10] See the similar interpretations—based on texts from Marshall's *Principles*—in Friedman (1949) and Patinkin (1963).

[11] See Archibald (1961) and the references to Stigler and Friedman there cited, as well as the subsequent exchange (1963) between all three of these economists. See also Miller (1962, p. 67).

growing over the course of human history. (See Knight, 1936, p. 434.) And a capital good has value only by virtue of its being the source of the stream of services—and hence of income—that flows from it.

The economic explanation of the rate of interest is to be found in the productivity of capital. Time preference is not a cause of interest, but the result of it; because interest can be earned by deferring present consumption to the future and investing the savings in the meantime, the individual can not be in equilibrium unless a dollar's worth of present consumption exceeded the value to him of a dollar's worth of future consumption by precisely the interest that could alternatively be earned by abstaining now from consumption. I should also note that Knight's emphasis on the fact that capital in the abstract—or wealth—was continuously growing over time led him to reject the Fisherine notion that individuals save in the present only in order to finance increased consumption in the future.

And since the rate of interest is determined by the productivity of capital, it is (as Lerner (1953), Haavelmo, and others were later to emphasize) the total *stock* of capital that is relevant to this analysis—and not the *flow* of current investment, which by its very nature is small relative to the total stock of existing capital, and hence can have little effect on its marginal productivity. (See Knight 1932a, pp. 262–63; 1936, p. 622.) (I might note that this concern with the time dimensions of the various economic variables was a constant characteristic of Knight's analysis—emphasized, for example, also in his treatment of the different "runs" of Marshallian cost and supply curves (Knight, 1921b, pp. 186–216).)

On the basis of this approach to capital theory, and with the aid of his historical perspective, Knight continued to insist—even in the face of the huge quantities of idle plant and equipment of the greatest depression in history, and the contrary contentions of the "secular stagnationists" who dominated economic thinking in the decade after the *General Theory*—that in the real world there is no tendency toward a diminishing return to capital, so that from the long-run viewpoint the demand for capital is infinitely elastic. Accordingly he rejected as unrealistic the classical notion of a long-run equilibrium quantity of capital that would characterize a stationary state to which the normal development of the economy would allegedly lead (Knight, 1936, 1944a).

These conclusions resulted from Knight's fundamental contention that the very process of increasing the stock of capital must of necessity change the "given conditions" which are supposed to generate diminishing returns. This contention was connected, first of all, with Knight's inclusive concept of capital as encompassing all factors of production, so that capital formation in the real world would lead to the augmentation of all productive agents, thus leaving no fixed factor which would be the source of diminishing returns.

Secondly, stressed Knight, ". . . it is practically impossible to imagine any investment activity in the real world which is not in some degree rationally experimental, in the sense of being reasonably expected to lead to new knowledge having some enduring economic significance. That is, all investment consists, in part, of investment in new knowledge." On the other hand, ". . . we can hardly think of new knowledge being applied without considerable accompanying expenditure on new instruments. This is even more unrealistic than the converse case, previously discussed" (1944a, pp. 40–42).

In brief, Knight's "growth model" was one in which all investment generates "learning by doing," and all technological change is "capital-embodied."

Finally, another factor acting against diminishing returns was the fact that wants did not remain constant, but were changing. "Moreover, it is a familiar fact that in real life much investment actually takes the form of creating or changing consumers' wants and that the result appears in the capital and profit-and-loss accounts of an enterprise" (Knight, 1944a, p. 37).

As an aside, I might conjecture that we can find in Knight's capital theory one of the main sources of his objections (on theoretical, as distinct from political, grounds) to Keynes' *General Theory*. Knight could not accept the implications of this book that the rate of interest was related to the flow of current investment, and not (as Knight had emphasized) the existing stock of capital. Nor could Knight entertain the notion of a long-run stagnating economy in which the rate of interest was driven down to zero. Finally, Keynes' presentation of the rate of interest as a monetary, and not a real, phenomenon was anathema to Knight (1937, pp. 112–13; 1941, p. 221–23; see also 1960, pp. 81, 92).

In any event, Knight's continued emphasis on the dynamic and progressive aspects of the real world—and hence the inappropriateness of analyzing it in terms of a static model—was one of the most important messages that he conveyed to his students. As already noted, he conveyed this message not only with respect to the conditions of production, but also with respect to those of demand. Thus Knight never tired of emphasizing that wants did not remain constant, but constantly expanded over time; that the concept of "minimum" or "subsistence needs" was not a physiological one, but the value judgment of a society at a given point of time as to what the minimum standard of living of its members should be; and that, accordingly, this minimum increased over time with the society's general standard of living. Correspondingly, emphasized Knight, the theory that wages were exogenously determined by the subsistence needs of workers was nonsense.

In this context Knight also contrasted the view on the adjustment of wants to available resources in Western culture, as contrasted with ascetic cultures, such as the Buddhist one: the former attempts to make the adjustment by increasing resources; the latter, by denying wants. And I seem to recall Knight's commenting that from the long-run viewpoint, this denial of wants was the only way that a definitive adjustment of wants to resources could be achieved: for history had shown that Western society created new wants just as fast as (if not faster than!) it expanded the means of satisfying them.

The social determination of wants was a theme that Knight also emphasized in his joint (with Charner M. Perry of the philosophy department) seminar on "Economics and Social Institutions" (Econ. 305). In this sense, then, Knight was an institutionalist. On the other hand, he was not an institutionalist in the sense of advocating the historical or statistical approaches to economics. On the contrary, as I indicated above, Knight's approach to economics was definitely non- (if not anti-) empirical. Indeed, I have a vague recollection of Knight (though it might have been Viner) referring to the excellent fits that have been achieved with the Cobb-Douglas function—and wryly adding that nobody really understood why such consistently good findings emerged from such variegated data![12] In a broader sense of the term, however, Knight was much concerned with empirical facts: and I am referring once again to Knight's insistence

[12] Still, one of the few instances in his writings in which Knight cited a statistical estimate of an economic magnitude was his citation of the Cobb-Douglas estimate of the elasticity of demand for capital! (1936, p. 623).

on basing his analysis of investment and of the wants that lie behind demand on what he discerned as the salient dynamic features of the real world.

These were some of the distinctive features of Knight's teaching of economic theory. Actually, however, he also conveyed these messages in his teaching of the "History of Economic Thought" (Econ. 302), where his detailed critique of the Ricardian system (1935a) was the vehicle by which Knight made clear the main features of his own analytical framework. For this reason this history was live and current for us as students. Here too, however, I must admit that part of this liveliness stemmed from our realizing that the evaluation of Ricardo was also the subject of a running debate between Knight and Viner, where in contrast with the analytical genius whom Viner depicted, Knight depicted a Ricardo who represented a retrogression from the achievements of Smith: primarily I think, because of what Knight regarded as Ricardo's greater emphasis on—and formalization of—the labor theory of value. Indeed, Smith—according to Knight—did *not* believe in the labor theory of value (Classnotes, Econ. 302, 1945).

Knight devoted most of his "History of Thought" course to the classical school, and in this connection had us read the relevant texts from Smith, Ricardo, Senior, and Mill. He then set us the task of presenting what we had learned about this school in a term paper (which had become a standard feature of the course) on "The Classical Cost-of-Production Theory of Price." The remainder of the course was devoted to the Austrian "subjective-value revolution," with a few passing remarks added with reference to the institutionalists. As already indicated, there was much overlapping between this course and Knight's theory course proper—though the emphasis of the latter was on the Marshallian synthesis of the classical and Austrian approaches.

There is one aspect of Knight's treatment of the history of economic thought that continues to puzzle me: despite Knight's broad historical interests—and his 1926 translation of Max Weber's *General Economic History*—Knight made practically no attempt to relate the development of economic thought to the contemporaneous historical developments. At one point in his "History of Economic Thought" course—after distinguishing several "epochs of economic thought"[13]—he went on to say that we "have to examine the historical contexts of the economic writings of these periods" (Classnotes, Econ. 302, 1945). But Knight himself did little further along these lines—except for some passing remarks in his discussion of Ricardo's work.[14] Instead, Knight's approach to the history of thought was that of providing a purely logical criticism of the nature of the assumption made by the various schools of thought, and the validity of the conclusions that they drew from them; he was concerned almost solely with the logical

[13] Namely: "I. Tribal Society and Ancient Empires—in which we do not know how much economic thought went on; II. Greece and Rome; III. Middle Ages; IV. Economic nationalism: Mercantilism (16th–18th centuries); and V. Individualism-liberalism" (Classnotes, Econ. 302, 1945).

[14] "Ricardo in the main was not interested in equilibrium theory, but in the reasons for historical changes: especially in the pressure of increasing population on increasing wealth and constant natural resources. Ricardo was interested in what happens to wages . . . If you project yourself to England of 1815 you can justify this somewhat in terms of what happened during Ricardo's life. About 1770 England began to export manufactured goods and import raw produce—whereas the converse was true before. There were great technological advances [in England]. Then the war cut off importation into England, and so had great increase in agricultural pressure on land. Ricardo was really thinking of revolutionary changes in relative value of agricultural and industrial products" (Classnotes, Econ. 302, 1945).

consistency of the theories he was examining.

At the beginning of this memoir I referred to Knight's humility—and he was indeed humble with respect to the limits of knowledge in general, and of economics in particular. ("I once asked a historian of medicine when he thought doctors began curing more people than they killed. 'Well' he answered, 'I think that that will be in another generation or so'.") But when it came to things that it was given to mortals to understand, Knight (as implied by my description here of his many disagreements with other economists) was a vigorous critic and polemicist—though more so in print and in formal lectures than in his classroom discussions. And even in those cases where it was Frank Knight against the field, we students were left in no doubt as to where the truth lay: "You can be with the majority—or you can be in the right."

II. Knight the Radical Economist—and the Conservative

The general image of Frank Knight in the profession is of a conservative economist whose outstanding students over the years (for example, Henry Simons in the 1920's, Milton Friedman and George Stigler in the 1930's, and James Buchanan in the 1940's) were and are among the leading representatives of this position. So it seems odd at first to think of Frank Knight as a radical economist—but that is one of the sharpest impressions that I have of him.

Knight was not, of course, a radical in the sense of being an advocate of Marxian economics: he had little patience with—and, indeed, had intellectual contempt for—the labor theory of value. His criticism of this theory was expressed in a general way in the course of his analysis of Ricardian economics, mentioned in the preceding section. But he also dealt in a direct—and pithy—manner with some of the basic Marxist tenets. And here Knight revealed one of his major strengths: his ability to make telling points by resorting to obvious facts—whose implications, however, were not at all obvious until he drew them out.

Thus, said Knight, it was "nonsense" to say that labor created capital: "Capital was produced by *capital and* labor working together. Capital is as old as labor" (Classnotes, Econ. 302, 1945, emphasis in original).

Similarly fallacious was the subsistence theory of wages. First of all (as noted above) "subsistence" was itself a changing social concept affected by economic circumstances, and not a fixed physiological concept that could exogenously determine the level of wages. Second, if an employer were indeed free to determine wages at any level he chose, then ". . . an employer will not pay a free laborer a wage high enough to enable him to raise children, since there is no guarantee for the employer to gain by it" (Classnotes, Econ. 302, 1945).

But for the modern economist Knight was—or, more accurately, could have been—a far more effective radical than Marx: for in contrast to Marx, Knight understood the workings of the market system, but he went on by a deeper analysis of these workings to deny the ethical foundations of this system. Indeed, there is little in the writings of the modern day "radical economists" as described, for example, by Lindbeck, that was not more trenchantly said by Knight in his famous essay—published exactly fifty years ago—on "The Ethics of Competition" (1923, especially pp. 45–58). To my mind, these thirteen pages are among the most radical ever written in economics, and even now they remain sharply imprinted in my memory as among the most exciting things that I read during my student days.

Knight's major point in these pages was

that "... in the conditions of real life no possible social order based upon a *laissez-faire* policy can justify the familiar ethical conclusions of apologetic economics" (1923, p. 49).

The reasons for this were, first of all, that

> ... the freest individual, the unencumbered male in the prime of life, is in no real sense an ultimate unit or social datum. He is in large measure a product of the economic system, which is a fundamental part of the cultural environment that has formed his desires and needs, given him whatever marketable productive capacities he has, and which largely controls his opportunities.... It is plainly contrary to fact to treat the individual as a datum, and it must be conceded that the lines along which a competitive economic order tends to form character are often far from being ethically ideal. [1923, pp. 49–50]

Hence (said Knight) it cannot serve as a justification of the market system simply to say that it produces goods that satisfy the wants of individuals in the economy; for a far more fundamental test of any system is the nature of the wants themselves that it produces. " 'Giving the public what it wants' usually means corrupting popular taste" (1923, p. 57).

Or, again, the statement that the market system "works efficiently" is a normative statement, and not a descriptive one: for, said Knight (making use, as he was wont to do, of homely analogies from the world of physics) by the law of conservation of energy, total output is always exactly equal to total input; hence "efficiency" has meaning only as a measure of *useful* output to input, which means that a value judgment must be made as to the "usefulness" of the output to society. The market system "gets things done"; yes, said Knight, but what things?

So it should not surprise us that long before the recently renewed emphasis on the limitations of "consumer sovereignty" (see, for example, John Kenneth Galbraith, pp. 202–28), Knight was emphasizing that wants are not only the product of the system in general, but can also be specifically influenced by advertising:

> ... skill in verbal utterance, or capacity in any form to "influence" other persons, is a form of economic power. Men have lived by their wits from time immemorial; it was no doubt one of the earliest uses of language. Persuasive power is, in the first place, a form of "productive capacity" in that skilful "puffing" makes a product more desirable to a purchaser and consumer, who in an individualistic system is the final judge of the merits of products.... Adam Smith and the classical economists, in advocating freedom of access to the market, do not seem to have thought about the possibilities of personal influence as a serious factor in economic relations; advertising and selling technique assumed importance after Smith's day [1935b, p. 292; see also 1923, p. 51, note]

Another deficiency of the market system is that it tends naturally towards monopoly:

> No error is more egregious than that of confounding freedom with free competition, as is not infrequently done. As elementary theory itself shows, the members of any economic group can always make more by combining than they can by competing. The workings of competition educate men progressively for monopoly, which is being achieved not merely by the "capitalist" producers of more and more commodities, but by labour in many fields, and in many branches of agriculture, while the producers of even the fundamental crops are already aspiring to the goal. [1923, p. 52]

(I should note that in later years Knight came to consider labor unions—with their growing power—as the most harmful form of monopoly in the economy (see for example (1960, pp. 168–70).)

Knight's sharpest shafts were reserved for his critique of "productivity ethics"—

the view (that Knight usually associated with the name of J. B. Clark) that one could attribute an ethical value to the income distribution generated by paying factors of production in accordance with their respective marginal products.

First of all, said Knight, because of market imperfections in the real world, "there is only a 'general tendency' to impute to each productive agent its true product" (1923, p. 55).

Second, the value of the marginal product depends on its price; and the

> money value of a product is a matter of the "demand," which in turn reflects the tastes and purchasing power of the buying public and the availability of substitute commodities. All these factors are largely created and controlled by the workings of the economic system itself, as already pointed out. Hence their results can have in themselves no ethical significance as standards for judging the system. [1923, p. 55]

And to these two points, Knight added his most trenchant criticism of all:

> The income does not go to "factors," but to their owners, and can in no case have more ethical justification than has the fact of ownership. The ownership of personal or material productive capacity is based upon a complex mixture of inheritance, luck, and effort, probably in that order of relative importance. What is the ideal distribution from the standpoint of absolute ethics may be disputed, but of the three considerations named certainly none but the effort can have ethical validity. [1923, p. 56]

Not only is there no ethical justification for the existing distribution of income (and, as can be seen from the preceding citation, Knight did not distinguish in this context between income from labor and income from property), but as a result of the cumulative processes at work in the market system, the distribution becomes increasingly worse:

> . . . where the family is the social unit, the inheritance of wealth, culture, educational advantages, and economic opportunities tend toward the progressive increase of inequality, with bad results for personality at both ends of the scale. [1923, p. 50]

These words were written in one of Knight's first articles, when he was a relatively young man (around 35). And I am sure that there will be those who will say that they represent the "radicalism of youth" which Knight later "outgrew."

To this I can only say (on the basis of my own classroom experiences) that even twenty years later Knight continued to consider these criticisms sufficiently important to convey in his lectures to his students.[15] Furthermore, he had earlier repeated many of them in his major essay on "The Ethics of Liberalism" (1939a, pp. 45–74). I also find it significant that—at the age of 65—he returned to these points in what was essentially a statement of his credo in his presidential address to the American Economic Association (1951). Similarly, in one of the last articles he wrote (1966),[16] Knight made use of the foregoing points (and others) to present a sharp criticism of a would-be justification for the capitalist system by Henry Hazlitt[17,18] Thus the evidence indicates

[15] These discussions recurred in all of Knight's courses. They were, however, particularly emphasized in a joint seminar (again, with Charner M. Perry) on "Economic Theory and Social Policy" (Econ. 304).

[16] I am indebted to Paul Samuelson for bringing this article to my attention.

[17] Several readers of the first draft of this memoir have called my attention to a lecture before a student group which Knight gave during the presidential elections of 1932 and which was entitled "The Case for Communism from the Standpoint of an Ex-Liberal," a lecture of whose existence I was not hitherto aware. The main burden of this lecture, however, was not Knight's ethical critique of the economic functioning of the capitalist system that has just been described, but a scathing criticism of the inability of a democracy to govern itself rationally and efficiently by means of discussion—from which Knight concluded that government by a communist dictatorship might be preferable. This emphasis is also clear from the general title under which this lecture—as well as two others that Knight

that Knight's fundamental ethical critique of the actual operation of the market economy was an essential part of his thinking throughout his life.

And so at the Chicago of my student days it was, ironically enough, the socialist Oskar Lange who extolled the beauties of the Paretian optimum achieved by a perfectly competitive market—and Frank Knight who in effect taught us that the deeper welfare implications of this optimum were indeed quite limited.

All of which raises the question as to the sharp contrast between Knight's incisive criticism of the existing system, and his basically conservative opposition to various proposals made to reform it, and all the more so to change it radically. For this conservatism, too, was a fundamental element of Knight's teachings. Thus after summarizing his ethical critique of the market system in his 1939 "Ethics of Liberalism," Knight went on to conclude that

> . . . society has strong reasons for maintaining powerful brakes on departures from the "beaten path." Primitive society was wise in its conservatism, for it knew at least that the group had previously lived somehow, both as individuals and as a group. And liberal society, it now seems, has acted frivolously in switching over quite suddenly to an extreme opposite set of assumptions, that the new is better than the old, that the good consists in change, or at least in freedom of the individual to make changes; rather than in stability. This emphasis on the necessity of an *onus probandi* in favour of conservatism and against change, must stand as our last word at this point. [1939a, p. 74; see also 1935b, p. 286]

Similarly, in his 1950 presidential address he emphasized that ". . . the possible amount and speed of free and intelligent social change will always be quite narrowly limited" (1951, p. 276).

In some cases Knight's opposition to reform proposals stemmed from his belief that the proposals in question failed to reveal a proper understanding of market forces. Thus he opposed price and rent controls because he felt that these reflected a failure to understand the functioning of the price system in allocating scarce resources. He was particularly critical of reform proposals that in his eyes committed the original sin of offering "something for nothing,"[19] and he continuously decried the age-old human fail-

gave before student groups at roughly the same time—were subsequently multilithed for private circulation: namely, *The Dilemma of Liberalism* (1933b). I might also note that Knight included the main substantive points of this criticism of the democratic process in his essay a few years later on "Economic Theory and Nationalism" (1935b), discussed below.

There is no copy of the *Dilemma of Liberalism* in the University of Chicago library, though there is a copy (to which I was directed by Maynard Kreuger) in the library of the London School of Economics. A copy (though without the title page) is also to be found among the papers that Knight left after him.

I might also note that the sections of the lecture on "The Case for Communism from the Standpoint of an Ex-Liberal" dealing with the genesis, character, and failures of the liberal regime (1933b, pp. 21–45) were reprinted in the eighth (1939) edition of the *Selected Readings* for the Social Science II survey course (Knight, 1939b). However, the title of the lecture from which these sections were taken (namely, "The Case for Communism . . .") is blackened out both in the Table of Contents of the *Selected Readings* and at the head of the reprinted sections, though it remains partly legible. A footnote attached to the blackened-out title indicates that the selection reprinted is an "excerpt from a privately printed pamphlet."

[18] I should, however, note the milder tone of some of these criticisms in Knight's 1960 book on *Intelligence and Democratic Action*, written as he approached the age of 75. Here Knight also wrote:

> I may say that in the three decades or so since I laboriously worked up a lecture on "The Ethics of Competition" (given at Harvard University and later published as an article in the *Quarterly Journal of Economics*—and still later reprinted in a book) I have done quite a lot of thinking about ethics and economics, and have perpetrated some wordage in print as well as in several university classrooms. As a result, I have become even more hesitant about speaking very definitely and positively. [1960, p. 122]

[19] From which view on life may have stemmed the more recent "Chicago tradition" that "there is no such thing as a free lunch."

ings that led to the belief in such a possibility. "A refrigerator generates cold," he would say in another one of his parables from physics, "only by conveying heat from the inside to some point on the outside. And people just never seem to be able to understand that simple fact."

But a far more basic source of Knight's conservatism was his view that as bad as the existing market system was, the alternatives were even worse! Indeed, this is the view to which he adverts in the concluding paragraph of his discussion in the aforementioned "thirteen pages" of his "Ethics of Competition":

> It is expressly excluded from the field of the present paper to pass any practical judgment upon the competitive system in comparison with any possible alternative. But in view of the negative tone of the discussion, it seems fair to remark that many of the evils and causes of trouble are inherent in all large-scale organization as such, irrespective of its form. It must be said also that radical critics of competition as a general basis of the economic order generally underestimate egregiously the danger of doing vastly worse. Finally, let us repeat that practically there is no question of the exclusive use or entire abolition of any of the fundamental methods of social organization, individualistic or socialistic. Economic and other activities will always be organized in all possible ways, and the problem is to find the right proportions between individualism and socialism and the various varieties of each, and to use each in its proper place. [1923, p. 58]

To the best of my knowledge, Knight never specified the criteria by which these "right proportions" were to be chosen—and I shall return to this point below. What I want now to explain is that the way in which Knight feared that the alternatives could ethically do "vastly worse" than the existing market system was primarily in their impact on individual freedom. For Knight, such freedom was an absolute value: even if people do not want freedom, they ought to want it. Furthermore (and here Knight's historical perspective reinforced his conservatism) liberalism and individual freedom were recent historical developments.[20] Indeed, they might even be said to have been the chance product of "a remarkable and temporary concourse of circumstances" that prevailed during the eighteenth and nineteenth centuries. Thus individual freedom was a fragile development—in constant danger of being destroyed (1935b, pp. 287–89, p. 305, note; see also 1960, pp. 38–39, 108).

"There has been, and must be, a question," said Knight in his critical review of Sumner Slichter's book in favor of economic planning[21]

> . . how far it is *comparatively* better social policy (I am aware of the redundancy but wish to be clear) to have individuals make their own choices in economic life and how far better to have them dictated—by anybody else who can be thought of in the position of dictating them. . . . What I want from the preachers of control, and do not get in [Slichter's] *Modern Economic Society* . . . or anywhere else, is something I can understand on the subject of *who* is to make the economic choices for the individual who admittedly makes them quite "imperfectly," or *how* this choosing functionary is to be selected, and *how* the individual affected is to be brought to accept them; and, in general, what kind of (a) individuals and (b) social order the preachers are either assuming or working toward. [1932b, pp. 823–24, italics in original]

Looking back on all this now, I would conjecture that an important additional element of Knight's fundamental conservatism—and general opposition to "planning" or other government action

[20] The Greek city-states with their slaves were, in Knight's eyes, hardly in this tradition.

[21] I am indebted to George Stigler for bringing this review article to my attention.

whose declared aim was the improvement of the actual workings of the market economy—was his view of the "system of individual freedom" as representing a stage of unstable equilibrium in the course of human history. (I think it is significant that the instability of various aspects of the macro-world is a recurrent element of Knight's thought: it is reflected, as we have seen, in his discussion of the cumulative tendencies toward inequality and monopoly in a market economy; it is also reflected in his discussion (to which I shall now turn) of the cumulative tendency toward the concentration of power; finally, in a different context to be discussed below, it is reflected in his view of the business cycle—and particularly of the cumulative movement in it of the absolute price level.) In view of the existence of this knife-edge equilibrium, Knight feared that any encroachment by the state upon individual freedom in the attempt to "improve" the economy would generate cumulative departures from this freedom.

Be that as it may, the specific ways in which he feared that one of the possible alternatives to the market system—"democratic socialism"[22]—could "do worse" were spelled out by Knight in his lengthy 1935 essay on "Economic Theory and Nationalism." Knight's point of departure was that socialism was the extension of the political process to the business world. But if this extension were carried out within a democratic framework (as its advocates claimed to be interested in doing) then

> . . . the essential point is that, as it has worked out in practice in the modern world, *democracy is competitive politics*, somewhat as free enterprise is competitive economics (though inherently a competition for a monopolistic position), and shows the same weaknesses as the latter. [1935b, p. 295, italics in original]

In particular, competitive politics cannot be described as a system devoted to satisfying the given wants of the public; for this system—even more than competitive economics—tries by "advertising" (i.e., campaigning and political propaganda in general), to influence and form these wants themselves. Or, as Knight had succinctly expressed himself a few years earlier in sharp criticism of Sumner Slichter's defence of planning, ". . . between business and politics, it is as easy and as reasonable to assert that corruption goes one way as the other. . . . Both finally 'give the people what they want,' after doing their utmost to make them want what they want to give" (1932, p. 476). And, once again, the nature of the wants so generated by competitive politics are of questionable ethical value: ". . . in politics the appeal is almost exclusively to the crowd" (1935b, p. 299). Similarly questionable are the human qualities promoted by competitive politics as a means of succeeding in them.

Finally, the system of competitive politics that characterizes democracy and "democratic socialism" in particular will tend to generate more inequality in the real sense of the term than does the system of competitive economics. For ". . . the significance of consumption itself is largely symbolic; the inequality which really hurts is the unequal distribution of dignity, prestige, and power" (1935b, pp. 308–309; see also p. 298, note). And to this must be added the fact that the abilities which make for success in competitive

[22] By which Knight meant a representative democracy that continued to make use of the market, but in which

> . . . entrepreneurs and property owners . . . would be replaced by administrative officials, who, like their prototypes, would theoretically have no discretionary power over production, the details of organization being determined, just as under the theory of enterprise, by consumers' choices. [1935b, p. 307]

Presumably, Knight had in mind the kind of socialist system that Fred Taylor had described in his 1928 AEA presidential address, and which Lange (1936, 1937) and Lerner (1937) were later to explicate in greater detail.

politics ". . . are more unequally distributed among men by nature than is economic ability or power of any other kind, and also tend more strongly to cumulative increase through their own exercise" (1935b, pp. 296–97).

Thus not only does power corrupt, but it corrupts cumulatively. Nor can free elections be considered as a safeguard against this cumulative concentration of power in the hands of political leaders:

> In view of the way in which psychological principles work in politics, equal suffrage (even if it is respected in practice) provides little or no guarantee of equality in that field. The overwhelming majorities rolled up in plebiscites (more or less fairly conducted) on the question of dictatorship show where the realities lie. [1935b, p. 297; see also pp. 308–09]

(It should be recalled that Knight was writing these words a few years after Hitler had democratically reached power in Germany—as had Mussolini before him in Italy.)

The depth and intensity of Knight's feelings on the issues discussed in the preceding pages are well represented in the following paragraph from Knight's presidential address—or his "sermon," as he denoted it:

> The plea of communism, like that of Christianity, is justice, under absolute authority, ignoring freedom. (The former does extol progress, and progress through science, both of which Christianity despised; by the same argument, communism is overtly less devoted to law and tradition, more openly claims the right to ignore or break the law.) For liberalism, the primary value is freedom, self-limited by laws made by the community, ideally by general assent, in practice by representatives elected by a voting majority—one of its dangers. The laws of a liberal state will also be general, non-specific, but in a sense quite different from the Golden Rule or Law of Universal Love. The familiar figure is "rules of the road," in contrast with instructions where and when and how to travel, whether arbitrary or conformable to a traditional practice. But such freedom must be sweepingly limited by measures, not only of a "police" character in a broad sense, but also designed to equip the individual and family for social life by implanting wants and tastes in general conformity with the culture and endowing each with a minimum of productive capacity (or ultimately with final goods) without which freedom is a form empty of content. To take these units as "given' is flagrantly contrary to essential facts of life and means ignoring the major social problem. It is along this line that eighteenth- and nineteenth-century liberalism went to an extreme that has provoked a reaction which threatens to engulf all freedom, and justice too, in the modern conception of it, if not to destroy civilization. Liberal states have been engaged, however, through their short life, in correcting this imbalance between freedom and justice; more intelligence and better judgment is our need, rather than any radical departure in method. [1951, pp. 277–78]

In concluding this discussion of Knight's political views, I would like to turn to a question that arises most naturally from it: what was the relationship between Knight and the "Chicago school"? From one viewpoint this is a rhetorical question: for in his emphasis on individual freedom as a basic value, Knight (together with Viner) can only be considered to be one of the "founding fathers" of this school. At the same time I think that Knight (as well as Viner) was less doctrinaire in his views than some of his younger colleagues and followers. And clearly Knight (and here he differed from Viner) did not have the policy-orientation that is one of the hallmarks of the Chicago school.[23]

[23] This should not be considered to be simply a reflection of the absence of an empirical orientation on the part of Knight. For Henry Simons and Lloyd Mints were not empirically oriented either.

Thus, as we have seen, Knight was sharply critical of the ethical deficiencies of the actual workings of the market system—and was particularly scornful of the "productivity ethics" by which this system was sometimes justified. Nor did he make an absolute distinction between "government by law" and "government by men"—for laws too are made by men. In particular, Knight emphasized that

> . . . the primary difficulty with the notion of law as an ethical principle or norm is that the content of the law itself can never be taken as simply "given," or beyond dispute, even at a given moment. . . . there was always and inevitably occasion for "interpreting" the law, in enforcing it, and also for making law outright, i.e., changing it, in consequence of changing conditions and standards. [1939a, pp. 62–63]

A similar picture holds with respect to the specific monetary policy with which the Chicago school of the 1930's and early 1940's is so strongly identified: namely, the contracyclical policy of adjusting the quantity of money so as to stabilize the price level. The rationale for this "monetary rule" had been developed most systematically during the 1930's by Henry Simons,[24] who continued to expound it in his courses and seminars with us on fiscal policy. And Lloyd Mints did the same thing in his courses on monetary theory and policy.

In contrast, as I have already shown in a paper on the monetary policy of the Chicago school,[25] though Knight recognized the importance of monetary disturbances in generating cycles of booms and depressions, he was skeptical about the extent to which these cycles could be controlled. As he expressed himself in one of his lectures:

> In medieval times men didn't look for remedies since they thought everything was from God who was good—so everything was good. Now science is the God—and we think that there must be a remedy for every disease. Maybe there is no answer to the business cycle: maybe we have to let it take its course. [Classnotes, Econ. 301, 1945]

Correspondingly, I think it fair to say that Knight was less convinced than his younger colleagues, Simons and Mints, about the efficacy of the monetary rule of stabilizing the price level as a means of combatting the cycle. Indeed, in one of his lectures Knight said that he did "not know how to stabilize the price level—and at what height to stabilize it" (Classnotes, Econ. 301, 1945). I might also note that on at least one occasion in later years Knight expressed his preference for "administrative discretion" rather than "rules" in the carrying out of monetary policy (1960, pp. 105–06).[26]

But in all this—as well as in his failure noted above to specify the criteria by which to decide upon "the right proportions between individualism and socialism"—I think that we must see the manifestation of yet another basic element of Knight's character: that in what he regarded as the inherent contradiction between thought and action, Knight remained forever the man of thought: always critical, always probing, always asking questions—and always deeply aware of the complexities and inertias of the real world, and hence skeptical about the ex-

[24] Simons had been a student of Knight's at the University of Iowa, and had followed him to Chicago in 1927 as a lecturer.

[25] (1969, pp. 96, note 13; 111–12; and 114–15.) In 1969, I sent a copy of this paper to Knight and asked him for his comments. But Knight replied that "to be quite frank, I'm very definitely 'retired' from economics"—and went on to write briefly about other matters, including his concern about the tensions in the Middle East. (Personal letter to author, dated March 19, 1969.)

[26] It might be noted that Viner (1962), too, expressed his preference for discretionary action on the part of the monetary authorities. On the general relation of Viner to the Chicago school, see Patinkin (1969, pp. 94, note 5; 96, note 13; and 113.)

tent to which man could by deliberate policy-actions improve it.[27]

III. Knight the Social Philosopher and the Man

In my introductory reminiscences, I mentioned that I had heard Knight's "Price and Distribution Theory" course twice—and there is a distinct difference between my classnotes from these two exposures: for whereas the first is filled primarily with economic matters proper, the second contains less of these, and more of long digressions on the nature of man and society—and God.

But I do not think that this difference between the classnotes necessarily reflects a difference in the actual emphasis of these two courses. Instead, I suspect that it reflects the difference that had taken place in me, the listener. For by the second time I took the course I had already had several courses in economic theory proper, and I had also come to understand that the unique contribution that Knight as a teacher had to make to students—and not only to students!—was precisely in his rambling "digressions" on the nature of the world.

One of his major concerns in these digressions was religion—a concern that undoubtedly stemmed from Knight's growing up in the deeply religious atmosphere of rural Illinois at the turn of the century. After his youth, Knight was fighting religion all his life, and his strongest and most violent language were reserved for expressing his anticlerical views.

There were several dimensions to these views. First, the irrationality of religion—and even more specifically, its ban on intellectual curiosity and the asking of questions, its insistence on accepting its tenets without further thought, All this was anathema to Frank Knight—the eternal asker of questions ("Do parents in primitive societies correct their children's grammar?").

But I think that an even more important cause of Knight's anticlericalism was the discrepancy between the declarations of organized religions and their behavior. Again in the words of his presidential address:

> In Christianity, surely, we find the supreme "irony of history": that an original teaching centered ethically in humility, meekness, self-denial, and self-sacrifice became organized into corporations whose dignitaries have hardly been matched for arrogant grasping, using, and flaunting of power and wealth and for insistence on prerogative to the borderline of worship. One turns to Dostoevski's famous speech of the Grand Inquisitor for any adequate portrayal of this situation and its sinister indications of the nature of human nature. [1951, p. 277]

I believe that it was because of his confrontation with this discrepancy in his own cultural heritage that Knight's anticlericalism expressed itself in anti-Christianity, and anti-Catholicism in particular. I feel (though I may be prejudiced) that he expressed less opposition to Judaism: not because he thought any better of Judaism as a religion, but because the historical development of Judaism had been such as to leave it (in Knight's life experience) without the institutional frame-

[27] The following words from Knight's last book, written as he approached the age of 75, are revealing:

> It has been said that fools ask questions and wise men answer them . . . To that indictment I must plead guilty, and also that of being better at criticizing other people's asking and answering than at doing either myself, and more addicted to the former role. But I have a defense. . . . I think the role fits in with the concept of democracy, that the function of the intellectual leader, in the difficult field of social philosophy and policy, is to clarify issues, or at most suggest possible solutions and perhaps arguments, pro and con. Answering is rather the task of Adam Smith's insidious and wily animal, the statesman or politician, which in a democracy means the ordinary citizen. [1960, p. 121]

work and consequent power that so aroused his wrath in the case of Christianity.

In this context it is also significant that (to the best of my knowledge) Knight did not criticize Buddhism or Islam or any other of the great world religions in the same way that he did Christianity: and, I suspect, for the same reason just indicated—namely, that he had not directly experienced and been irritated by the workings of their institutional frameworks.

Here too we find the kind of contradiction in Knight's views that I noted above with respect to the question of social reform. He was highly critical of religion—and yet he recognized the vital function that it performed in maintaining the stability of any society: because the possibilities of social reform were limited—and could take place only slowly without endangering the existence of society—"men will always require—as a condition for maintaining any high civilization at all, some 'opiate' or some effective agent to prevent their demanding their rights" (1951, p. 276).

But if Knight was not a religious person in those things that concern man and God, in the things that concern man and man he exemplified the ethical qualities of moral rectitude and personal integrity that all religions teach us to aspire to. And he was an incessant and unswerving Seeker after the Truth.

I have mentioned Knight's opposition to the irrationality of religion. At the same time, however, he was the very opposite of those who turned rationality itself into a religion. Indeed, for Knight the very desire for rationality was one of the expressions of man's romantic nature. Knight never tired of quoting the saying—that he attributed to J. M. Clark (p. 24)—about the "irrational passion for dispassionate rationality." And he always reminded us that it was not the people of low intelligence who spent their lives squaring the circle and inventing perpetual-motion machines.

Similarly, as already noted, he was deeply skeptical of the extent to which rational discussion could solve social problems: in part, because of the intrinsic difficulty of these problems themselves; but even more so because of the difficulty of reaching a consensus; and the more intelligent people were, the finer the distinctions they would insist on making, and hence the less likely they were to achieve such a consensus. And perhaps most important of all: free discussion in a democracy would not remain rational, but would degenerate into demagoguery: "Cheaper talk drives out of circulation that which is less cheap"—so "Frank Knight's First Law of Talk" (1933b, p. 8).

Indeed, here we find the deepest contradiction in Knight's view of human society: on the one hand, he regarded individual freedom as a basic value, and recognized that representative democracy was the only way in which a large society of free individuals could govern itself; on the other, he had basic misgivings about the actual workings of the democratic process—and was accordingly deeply pessimistic about its future. So much so that on some occasions he predicted the "natural" disintegration of democracy and its replacement by dictatorship.

Another of Knight's major themes (and an important component of his anti-religious position) was that it was not enough to want to do good: one had to have an understanding of the workings of social forces in order to be able actually to do good. The church might outlaw usury as unjust: but because of the workings of market forces all that this prohibition did was to change the form in which income from property was received—from the form of interest to that of rents or profits.

The government might—in the face of "shortages" of critical goods—impose price controls: but this would not increase the quantities of these goods, and would indeed create artificial scarcities.

And "love thy neighbor as thyself" was not a prescription for social action. How do you know that your neighbor has the same tastes as you do? More important—to love everybody is to love nobody: for love is a differential relationship.[28]

Knight was deeply concerned with the personal element of morality and the ethical problems created by an impersonal society. No one (Knight once said) would reinsert his coin into a public phone if it were accidentally returned to him after the completion of his call; indeed, if he were to do so, he would be considered a fool—not a saint. But was not this stealing?

Cynical? Perhaps. Though not the cynicism of an embittered man, but the cynicism of one who looked with understanding—and, though he would probably have denied it, even compassion—on the limitations of man and society. The cynicism of one who had resigned himself to the limitations of *la condition humaine*.

He was—as has been said of Ecclesiastes—a gentle cynic.

Labor Hoarding in Durable Goods Industries

By C. Scott Clark*

Most economists are familiar with the observed short-run behavior of productivity as measured by output per man or output per man-hour. It is generally observed that productivity tends to rise most rapidly when output is recovering towards capacity and to fall or rise less rapidly as output declines from capacity. According to the law of diminishing marginal productivity, however, the opposite behavior should be observed. That is, with capital fixed in the short run, there should be decreasing returns to labor as output increases towards capacity and increasing returns to labor as output declines from capacity. This apparent contradiction between reality and theory has not been confined solely to studies of how output fluctuates with employment. Econometric studies of short-run employment behavior have consistently obtained estimates of the equilibrium output-employment elasticity which suggest increasing returns to labor services (see Robert Ball and E. B. A. St. Cyr, Frank Brechling, David Smyth and N. J. Ireland, and Robert Solow).

A number of hypotheses have been put forward in an attempt to reconcile this apparent paradox (see Ray Fair, Edwin Kuh, and Robert Solow). One possible explanation, which recently has begun to attract an increasing amount of support, is referred to as the labor-hoarding theory. This theory operates on the assumption that there are important costs associated with changing the labor force. Given these adjustment costs, a minimum cost employment policy for a firm may be one in which the firm employs more labor during periods of declining output than is required to produce the desired level of output. If this hypothesis is true, then during periods of declining output the actual labor used in the production process may in fact be declining in proportion or more than in proportion to changes in the output even though measured employment does not. At the same time, once output begins to recover, the increase in measured employment will be less than proportionate to the increase in output because the firm can now use in its production the excess labor that was accumulated during the previous periods of declining output. The fact that measured employment may not be a very good measure of the true production function input could very well account for the contradictory results obtained by the earlier productivity and short-run employment studies.

The purpose of this paper is to construct a model of short-run employment behavior in durable goods industries based on an assumption of labor hoarding. The paper is composed of four sections. In Section I the labor-hoarding model is developed assuming perfect foresight, and the necessary and sufficient conditions for a minimum cost employment policy are established. Using the cost minimization conditions, a programming algorithm is derived which permits us to obtain estimates of the maximum length of time it would be profitable for firms to hoard excess labor, referred to as the labor-hoarding lag. Two models are constructed. The first model

* Assistant professor, University of Western Ontario.
I am indebted to Robert E. Hall for many helpful comments and criticisms, and to Stephen B. Browne for invaluable research assistance.

assumes there is no production lag in durable goods industries, while the second model allows for a production lag in the determination of required employment. In Section II the data are described. Section III presents the estimates of the labor-hoarding lags. Several hypotheses are also tested. Section IV contains the summary and conclusions.

I. The Models

We assume that the objective of the firm is to produce output $Q_1, Q_2, \ldots, Q_T$ over T periods at least cost. We also assume that the production function of the firm is such that a fixed number of workers is required per unit of output.[1] That is:

$$L_t \geqq \lambda Q_t \tag{1}$$

where L_t is the number of workers employed by the firm during period t, Q_t is the firm's output, and λ the production coefficient or labor-output ratio.[2]

We postulate that there are three costs associated with using labor: a wage, w, paid each period; a hiring cost, h, paid each time the labor force is enlarged; and a layoff cost, f, paid each time the labor force is reduced.[3] The firm's total labor cost over T periods is thus:[4]

$$\begin{aligned} C = {} & w(L_1 + L_2 +, \ldots, + L_T) \\ & + h([L_1 - L_0]^+ \\ & + [L_2 - L_1]^+ +, \ldots, \\ & + [L_T - L_{T-1}]^+) + f([L_0 - L_1]^+ \\ & + [L_1 - L_2]^+ +, \ldots, \\ & + [L_{T-1} - L_T]^+) \end{aligned} \tag{2}$$

where

$$\begin{aligned} [X]^+ &= 0 \qquad \text{if } X < 0 \\ &= X \qquad \text{if } X \geqq 0 \end{aligned}$$

Given (1) and (2), the necessary and

[1] The use of a fixed coefficient production function implies that capital and labor are not substitutable and therefore that variation in relative factor prices are not important in determining factor intensities. The large body of empirical work on production functions indicates, however, that manufacturing industries are characterized by factor substitutability. This would appear to indicate that the assumption of constant factor proportions for determining required employment is inappropriate. However, this is not necessarily so. It is not a contradiction to believe the empirical evidence which indicates that the true production technology is characterized by factor substitutability and at the same time still believe that, for the purpose of deducing factor demand from output demand, a fixed coefficient technology provides a satisfactory approximation to the true technology. Factor substitutability may not be important for the purpose of deducing factor demand if relative factor prices do not change very much. There are, of course, some practical reasons for using the fixed coefficient approximation. First, because of the estimation technique used, it is important to keep the number of structural parameters to be estimated to a minimum. Second, data for three-digit SIC industries are used in this paper, and there are, to date, no capital data available at this level of disaggregation.

[2] In constructing both labor-hoarding models in this paper, we have not allowed for substitution between the stock variable, workers, and the flow variable, the number of hours worked per worker. In our models, an increase or decrease in shipments and new orders necessitates an increase or decrease in required workers. This excludes the possibility of simply changing the utilization of the existing stock of workers (i.e., the number of hours worked per worker) in response to a change in shipments or new orders.

[3] Hiring costs are usually defined as including recruiting costs, orientation costs, recalling costs, training costs, and so forth. Layoff costs will include severance pay, that part of training costs that will not be recouped if the worker is laid off, and also unobservable costs such as bad worker morale, bad community relations, and union conflicts.

[4] We could have included a discount rate in our cost function. Assuming a constant discount rate, r, total discounted labor cost is:

$$\begin{aligned} C = {} & \sum_{t=1}^{T} \frac{wL_t}{(1+r)^t} + \sum_{t=1}^{T-1} \frac{h[L_t - L_{t-1}]^+}{(1+r)^t} \\ & + \sum_{t=1}^{T} \frac{f[L_{t-1} - L_t]^+}{(1+r)^t} \end{aligned}$$

The inclusion of the discount rate does not affect the derivation of the labor-hoarding lag t*. We would now have for any t that,

$$\frac{(h+f)/(1+r)^t}{w/(1+r)^t} = \frac{h+f}{w} = t^*$$

That is to say, when considering the ratio of two nominal values discounted at the same rate, we need consider only the ratio of the two nominal values.

sufficient conditions for a cost minimization employment policy can be derived as follows. In general, a firm will hold no more labor than is required to produce current output, except that workers will not be laid off for a temporary drop in output. The maximum length of time that is profitable for a firm to keep a worker on the payroll without having him work is given by the ratio of the layoff plus hiring cost to the wage cost. That is:

$$t^* = \frac{h + f}{w} \tag{3}$$

In other words, a minimum cost employment policy for a firm is one in which the firm will never have more than t* successive periods of positive excess labor. At the same time, in order for employment costs to be minimized, a layoff by a firm will never be followed by a hire within t* periods, since in that case it would be cheaper for the firm to eliminate both the layoff and the hire and carry excess labor. These two conditions are necessary and sufficient for a cost minimization employment policy. The interpretation of t* as the maximum length of time for which it would be profitable for a firm to hoard idle workers implies that the firm has perfect knowledge of its future output and consequently, from the production function, the path of required employment. This assumption of perfect foresight is implied in the specification of the cost function which includes future values of labor inputs. Without such knowledge, the firm would be unable to know exactly when it should begin hoarding labor or how much labor it should hoard. For the durable goods industries used in this study, the assumption of perfect foresight can be defended on two grounds. First, these durable goods industries produce primarily to order, and the lag between orders and production is sufficiently long to enable the firm to use its orders data in planning layoffs and hiring. Second, on the basis of past experience, firms have sufficiently good knowledge of the seasonal behavior of orders and shipments to permit accurate employment planning. If firms are fairly accurate in their forecasting, then the perfect foresight assumption might be a better approximation of how expectations are formed than hypotheses of imperfect expectations.[5]

An easy algorithm for estimating the labor-hoarding lag, t*, and the production coefficient, λ, is suggested by the two cost minimization conditions. We begin by taking as our initial guess of the firm's employment policy, the policy of holding no excess labor. In this case, we have from the production function that:

$$L_t = \lambda Q_t \tag{4}$$

Given data on output, and assuming a value for λ, we calculate the employment series that would occur if no excess labor were held. We then assume a value for t* and consider the earliest layoff (decline in employment) in the no excess labor employment series. If a hire (increase in employment) occurs within t* periods after the layoff, then the layoff and the hire are cancelled and the labor force increased for every intermediate period. This process is repeated over the entire sample until no hire occurs within t* periods of any layoff. At every iteration, the second cost minimization condition is satisfied so that the process will reach a minimum cost policy in a finite number of iterations. We select the maximum likelihood estimates of t* and λ from the set of all possible

[5] One method by which uncertainty could be introduced into the model would be to specify the production function in terms of expected output and expected employment. Alternative expectational hypotheses could be derived in terms of actual output. Such a procedure would certainly be necessary for industries which produce to stock but not necessarily for those which produce to order, which is the case for the industries used in this paper.

combinations by comparing the sum of squared residuals between the observed employment series and the estimated employment series based on our cost minimization conditions.

A brief examination of the employment-output data indicates that for most of the industries there has been a downward trend in the labor-output ratio. Having assumed away capital-labor substitution, there are two other possible explanations for this behavior. First, it is quite possible that the production function is one of increasing returns to scale rather than constant returns to scale. That is:

$$L_t \geqq \lambda Q_t^{\eta}, \qquad \eta < 1 \tag{5}$$

A second possible explanation is that there has been labor-augmenting technological change during the sample period. Allowing for this possibility, the technology approximation becomes:

$$L_t \geqq \lambda(t) Q_t \tag{6}$$

In this paper we adopt the second possibility. We assume that technological change takes place smoothly at a constant rate m, so that:

$$\lambda(t) = \lambda_0 e^{-mt} \tag{7}$$

Equations (6) and (7) simply say that a given level of output can now be obtained from a given capital input and a labor input, L_t, measured in men, that decreases over time. Within this model, a decreasing number of men represents an increasing number of labor efficiency units so that a fixed coefficient production relation is maintained between capital and labor efficiency units.

The labor-hoarding lag, t*, will be estimated using data for five three-digit SIC durable goods industries. By using three-digit industry data, it is possible to avoid some of the problems that might be caused by aggregation. It is very likely that many of the diverse relationships that exist between industries would be concealed if aggregate data were used. The use of three-digit industry data, however, does have some costs associated with it. Most important inventories by stage of fabrication are not available for three-digit industries. Consequently, it is necessary to use shipments as a measure of output. Since most of the durable goods industries used in this paper produce primarily to order, the assumption of no finished goods inventories is not unreasonable.[6] It is difficult to determine, however, what change in our output measure would occur if we were able to include the change in work-in-process inventories. It is quite possible that a decline in shipments could be completely offset by a build-up in work-in-process inventories so that output, as measured by shipments plus the change in work-in-process inventories, would show no decline, whereas output, as measured by shipments, would. This possibility would be particularly true for industries with fairly long production lags. If production of a good takes several periods, then the amount of labor required in any period will depend not only on the goods which reach completion and are shipped, but also on those goods still in the production process at different stages of completion (i.e., work-in-process inventories). To assume that required labor services depend only on shipments in the current period implies that there is no production lag.

There is sufficient evidence to indicate that in the durable goods industries production does take time. Consequently, in order to compensate for the possible inadequacy of shipments as a measure of output in this type of industry, we will develop a second labor-hoarding model based on the assumption of a production

[6] The possible exceptions are the blast furnaces and steel mills industry and the electrical distribution equipment industry.

lag. The second model is developed for an industry which produces $q+1$ different goods. Each good is distinguished by its production time, defined as the time between initiation of production and the completion of the final product.

We define the following variables:

$X_{t,j}$ = The value of production initiations of good j in period t

$L_{t,j}$ = The number of workers required during period t for the production of good j

As before, we assume that a fixed coefficient technology provides a satisfactory approximation to the true industry production function. More specifically, we assume that for good j a fixed number of workers is required per unit of production initiations of good j.

Consider now the demand for workers in period t to be used in the production of good j. In period t there will be some of good j reaching the final stage of production. These will be goods whose production was initiated in period $t-j$ (i.e., $X_{t-j,j}$). These goods will require some labor services. At the same time, there will be some of good j which will reach the final stage of production in period $t+1$. These goods whose production was initiated in period $t-j+1$ will also require some labor input. Thus, for each production of good j initiated in the current period and over the past j periods, there will be some labor input required in period t. Employment required for the production of good j in period t can then be written as a distributed lag function of production initiations of good j:

$$L_{t,j} = \sum_{\tau=0}^{j} \beta_\tau^{L,j} X_{t-\tau,j} \tag{8}$$

For $j=0$, the lag function would collapse to include only $X_{t,0}$:

$$L_{t,0} = \beta_0^{L,0} X_{t,0} \tag{9}$$

For $j=1$, we would have the relation:

$$L_{t,1} = \beta_0^{L,1} X_{t,1} + \beta_1^{L,1} X_{t-1,1} \tag{10}$$

Since there are $q+1$ goods there would be $q+1$ distributed lag labor requirement functions. Using a lag operator Z, equation (8) can be rewritten as:

$$L_{t,j} = \sum_{\tau=0}^{j} \beta_\tau^{L,j} Z^\tau X_{t,j} \tag{11}$$

Letting $\beta^{L,j}(Z) = \sum_{\tau=0}^{j} \beta_\tau^{L,j} Z^\tau$ we have the final labor requirement function for good j:

$$L_{t,j} = \beta^{L,j}(Z) X_{t,j} \tag{12}$$

Total labor required by the industry in period t is the sum of the labor requirements for each of the $q+1$ goods:

$$L_t = \sum_{j=0}^{q} \beta^{L,j}(Z) X_{t,j} \tag{13}$$

We now make the aggregation assumption that the mix of production initiations (i.e., $X_{t,0}, X_{t,1}, \ldots, X_{t,q}$) is constant for all t. That is:

$$X_{t,j} = \beta_j^p X_t \qquad (j = 0, 1, \ldots, q) \tag{14}$$

where X_t is the value of total production initiations in period t and the β_j^p measure the relative importance of the production initiations of each good. By definition:

$$\sum_{j=0}^{q} \beta_j^p = 1 \tag{15}$$

Substituting the aggregation assumption into (13) gives:

$$L_t = \sum_{j=0}^{q} \beta^{L,j}(Z) \beta_j^p X_t \tag{16}$$

Letting $\beta^L(Z) = \sum_{j=0}^{q} \beta^{L,j}(Z)\beta_j^p$ we have the final distributed lag relation between total labor requirements and the value of total production initiations:

$$L_t = \beta^L(Z) X_t \tag{17}$$

In the labor requirement equation, (17), the key variable (production initiations) is not observable. To complete the model for empirical testing we must relate X_t to some observable variable. In this paper, X_t is equated to the value of new orders received during period t. The labor requirement function then becomes:

$$L_t = \beta^L(Z)N_t \tag{18}$$

The lag function, $\beta^L(Z)$, is assumed to be stationary. The choice of new orders as a measure of production initiations in any period could result in situations, however, in which this assumption is not valid. If an industry is operating at less than full capacity, then any new orders received during a period can be initiated into production almost immediately. On the other hand, when capacity is being fully utilized, new orders will not be initiated immediately but instead will be placed in a queue to await production sometime in the future. Consequently, in addition to the work-time lag, there is now a wait-time lag. The latter lag component will vary over time depending on the degree of capacity utilization. In order for the stationarity assumption to be valid, we must assume that there is always sufficient excess capacity in the industries so that the wait-time lag is zero.[7] There are other reasons why the lag function may not be stationary. Even if there is excess capacity so that there is no queue, the work-time lag may change. First, there may be technological improvements resulting in a shortening of the work-time required for production. Secondly, there may be a cyclical response in work time. As demand conditions improve, firms may be able to shorten their work time by increasing their work speed. However, if demand continues to rise at a fairly rapid rate, there may be a relative deterioration in the earlier improvement as less efficient capital and labor must be employed. Finally, there may be a change in the relative importance of the various commodities in total demand.[8]

We can now complete the second labor-hoarding model. We assume that the objective of the firm is to fill all new orders $N_1, N_2, \ldots, N_T$, over T periods at least cost. Based on the assumption of a production lag and a fixed coefficient technology, the number of workers employed in period t is given as:

$$L_t \geqq \beta^L(Z)N_t \tag{19}$$

The cost function, (2), used in the first model is also applicable in this model. Since only the labor requirement function has been changed, the necessary and sufficient conditions for a cost minimization employment policy are essentially the same as those in the first model. In general, a firm will hold no more labor than is required to complete the production of

[7] This problem has arisen in other empirical work dealing with the distributed lag relationship between shipments and new orders. A number of investigators in this area attempted to allow for nonstationarity by using an estimation method known as variable weighted distributed lags (see Joel Popkin and Peter Tinsley). This approach to the problem is somewhat *ad hoc* in that models are not usually based on a convincing underlying behavioral hypothesis. A second alternative is to allow for varying capacity utilization through the specification of production initiations. For example, we might let $X_t = \text{Min}\,(C_t, Q_t)$ where C_t is capacity and Q_t the queue of unfilled orders for which production has not been initiated at the beginning of period t. This model implies a switching between two functions; when there is excess capacity, production initiations are equal to Q_t; when there is a capacity constraint, production initiations are then equal to C_t.

[8] It is easy to demonstrate that the labor requirement function in (4) is a constrained form of the more general case given in (18). If we adopt the assumption that there is no production lag there will be only one good produced in the industry (i.e., good 0). This implies that $X_{t,0} = X_t$. Equating production initiations to new orders gives $X_t = N_t$. Since we are also assuming no wait-time lag, every new order in period t becomes a shipment in period t: $N_t = S_t$. The labor requirement function is then simply $L_t = \beta_0^{L,0} S_t$ which is identical to equation (4).

those goods in the final stages of processing:

$$N_{t,0},\ N_{t-1,1},\ \ldots,\ N_{t-q,q} \tag{20}$$

and also labor required to maintain work on goods which will reach completion in periods t+1, t+2, . . . , t+q:

$$\begin{aligned} &N_{t,1} \\ &N_{t,2},\ N_{t-1,2} \\ &\vdots \\ &N_{t,q},\ N_{t-1,q},\ \ldots,\ N_{t-q+1,q} \end{aligned} \tag{21}$$

On the other hand, workers will not be laid off for a temporary drop in new orders. The maximum length of time that is profitable for a firm to keep a worker on the payroll without having him work is given by the ratio of the layoff plus hiring cost to the wage cost:

$$t^* = \frac{h+f}{w} \tag{22}$$

The necessary and sufficient conditions for a minimum cost employment policy are the same as in the first model. A firm will never have more than t* successive periods of excess labor. Moreover a layoff by a firm will never be followed by a hire within t* periods, since it would then be cheaper to eliminate both the layoff and the hire and carry excess labor.

To estimate the labor-hoarding lag, t*, we employ the algorithm described above. Three different specifications of $\beta^L(Z)$ will be used. To begin with, we adopt the simple specification that the lag coefficients correspond to a rectangular lag function. This can be expressed as:

$$\begin{aligned} \beta_\tau &= \alpha \qquad \text{if } 0 \leqq \tau \leqq q \\ &= 0 \qquad \text{otherwise} \end{aligned} \tag{23}$$

The labor requirement function then becomes:

$$L_t = \alpha \sum_{\tau=0}^{q} N_{t-\tau} \tag{24}$$

leaving only three parameters to be estimated: α, q, and t*.

Assuming values for α and q, we obtain an estimate of the no excess labor series from (24). With this series, we are then able to estimate the labor-hoarding lag, t*, using the cost minimization algorithm. Initial estimates of α, for different values of q, can be obtained by dividing the observed employment series by $\sum_{\tau=0}^{q} N_{t-\tau}$. Once having obtained the best estimates of α and t*, for each q, we select as our best estimates of all three parameters that equation which has the smallest variance corrected for degrees of freedom.

The second lag function to be used in this study is the inverted V or symmetric triangle. Using this specification, the lag coefficients are given by:

$$\begin{aligned} \beta_\tau &= \alpha_1\tau & 0 \leqq \tau \leqq \alpha_2 \\ &= \alpha_1\alpha_2 - \alpha_1(\tau - \alpha_2) & \alpha_2 < \tau \leq 2\alpha_2 \end{aligned} \tag{25}$$

where α_1 is the slope of the triangle and $2\alpha_2$ its length. Substituting this specification into the labor requirement function gives:

$$\begin{aligned} L_t = \alpha_1 &\sum_{\tau=0}^{\alpha_2} \tau N_{t-\tau} \\ &+ \sum_{\tau=\alpha_2+1}^{2\alpha_2} [\alpha_1\alpha_2 - \alpha_1(\tau - \alpha_2)] N_{t-\tau} \end{aligned} \tag{26}$$

Since the triangle is symmetric, this is equivalent to:

$$\begin{aligned} L_t = \alpha_1 &\sum_{\tau=0}^{\alpha_2-1} \tau (N_{t-\tau} + N_{t-2\alpha_2+\tau}) \\ &+ \alpha_1\alpha_2 N_{t-\alpha_2} \end{aligned} \tag{27}$$

In the case of the triangle there are three parameters to estimate: the slope α_1, the mid-point of the triangle α_2, and t*.

The estimation of the model with a triangular lag function is similar to that with the rectangle. Assuming values for α_2 and α_1, we obtain an estimate of the no excess labor series from (27). The labor-

hoarding lag, t*, is then estimated as before. We select as our best estimates of α_1, α_2, and t* that equation with the smallest variance corrected for degrees of freedom. Initial estimates of the slope, α_1, for different values of α_2, can be obtained by dividing observed employment series by:

$$\sum_{\tau=0}^{\alpha_2-1} \tau(N_{t-\tau} + N_{t-2\alpha_2+\tau}) + \alpha_2 N_{t-\alpha_2} \tag{28}$$

The third distributed lag function to be used in our labor requirement equation is the common geometric function. Under this specification, the coefficients are given by:

$$\beta_\tau = \alpha_1 \alpha_2^\tau \qquad 0 \leq \alpha_2 < 1 \tag{29}$$

The labor requirement function becomes:

$$L_t = \alpha_1 \sum_{\tau=0}^{\infty} \alpha_2^\tau N_{t-\tau} \tag{30}$$

Using a Koyck transformation, we obtain the labor requirement equation to be used in estimation:

$$L_t = \alpha_1 N_t + \alpha_2 L_{t-1} \tag{31}$$

With the geometric lag function, there are three parameters to be estimated; α_1, α_2, and t*. Initial estimates of α_1 and α_2 can be obtained in the following manner. First, we know that α_2 must be less than one and equal to or greater than zero. Assuming a value for α_2 within these bounds, we obtain an estimate of the range of α_1 by dividing observed employment by:

$$\sum_{\tau=0}^{K} \alpha_2^\tau N_{t-\tau} \tag{32}$$

where K is a constant inserted to make the sum finite. The larger K is, the better (32) approximates the infinite sum in (30).

There is, however, one additional estimation problem. It is necessary in the case of the geometric lag function to have an estimate of the number of nonidle workers held in period zero (i.e., L_0). In other words, it is necessary to consider different initial values for for L_0 and for each value obtain the best estimates of α_1, α_2, and t*. We select as our best estimates of L_0, α_1, α_2, and t*, that equation which has the smallest variance corrected for degrees of freedom.

So far in our discussion of this model, we have not considered technological change. We now assume that technological change takes place smoothly at a constant rate, m, so that employment is now given by:

$$L_t \geq \lambda_0 e^{-mt} \beta^L(Z) N_t \tag{33}$$

This results in one additional parameter to be estimated for each of the three distributed lag functions.

With technological change and a rectangular lag function, the labor requirement equation becomes:

$$L_t = \alpha e^{-mt} \sum_{\tau=0}^{q} N_{t-\tau} \tag{34}$$

In the case of the triangular lag function, using (27), we have:

$$L_t = \alpha_1 e^{-mt} \left[\sum_{\tau=0}^{\alpha_2-1} \tau(N_{t-\tau} + N_{t-2\alpha_2+\tau}) + \alpha_2 N_{t-\alpha_2} \right] \tag{35}$$

For the geometric lag function, the inclusion of technological change gives:

$$L_t = \alpha_1 e^{-mt} \sum_{\tau=0}^{\infty} \alpha_2^\tau N_{t-\tau} \tag{36}$$

Employing a Koyck transformation we obtain:

$$L_t = \alpha_1 e^{-mt} N_t + \alpha_2 L_{t-1} \tag{37}$$

The introduction of technological change in this manner allows the lag func-

tions in the labor requirement equation to be semi-nonstationary. For example, in the case of the rectangle, the inclusion of technological change implies that the height of the rectangle is decreasing over time, whereas in the case of the triangle, it implies that the slope is decreasing over time. In both cases, however, the length of the production lag remains constant. For the geometric lag function, the inclusion of technological change implies that the height of the function is declining.

In Section III estimates of the labor-hoarding lag are presented based on equations (6), (34), (35), and (37).

II. Data

The labor-hoarding lag, t^*, is estimated for the following three-digit SIC durable goods industries:

331—Blast furnaces and steel mills[9]
351—Engines and turbines
353—Construction, mining, and material handling equipment
354—Metal working machinery
361—Electrical distribution equipment

The shipments and new orders data are monthly unseasonally adjusted data obtained from the monthly survey of manufacturers published by the U. S. Department of Commerce. The data were not seasonally adjusted since the purpose of this paper is to examine the short-run behavior of employment. The sample used in this study covers the period January 1960 to January 1969. This includes one recession, 1960–61; the moderate expansion beginning late in 1961 and culminating in the more rapid expansion of 1965 and early 1966; the mini-recession of 1967 followed by a period of moderate growth until the beginning of 1969.

To obtain constant dollar shipments and new orders series, wholesale price indices published by the Bureau of Labor Statistics (*BLS*) were used. Unfortunately, the industry classifications used by *BLS* are not the same as the SIC classifications used by the Department of Commerce for its shipments data. It was not until 1967 that the Bureau of Labor Statistics began to publish wholesale price indices on an SIC basis. As a result, it was necessary to combine *BLS* price indices which would represent as much as possible the SIC industry.

Employment data are available for SIC industry classifications. There were some differences, however, between the industry classifications used by the Department of Labor and the classifications used by the Department of Commerce. The differences applied only to industry 354, metal working machinery, and industry 361, electrical distribution equipment. Fortunately, however, the employment data are available for four-digit industry classifications so that it was possible to derive employment series for industries 354 and 361 which are comparable to the industry classifications on which the shipments and new orders data are based. Both total employment and employment of production workers are available for our sample period. An estimate of employment of nonproduction workers is obtained as the difference between total employment and employment of production workers.

III. Empirical Results

Table 1 contains the best estimates of the labor-hoarding lag, t^*, for the four models estimated.[10] For the model with-

[9] The name of this industry classification is misleading. Unlike the other industries, the name of industry 331 does not refer to the output but to the means used to produce output. The output of this industry consists of ferrous and nonferrous alloy and finished and semi-finished steel products.

[10] The ranges over which the parameters were allowed to vary were large enough to insure that the best estimates were obtained. The ranges differed, of course,

Note: s = Variance adjusted for degrees of freedom computed from the sum of squared residuals between the observed employment series and the estimated employment series based on the cost minimization conditions.

[a] These estimates are not based on complete convergence of the variance (see fn. 10).

[b] The critical value of $\chi^2(1)$ at the .05 level is 3.84. Equation (38) in the text defines the test-statistic Z.

out a production lag, estimates of the labor-hoarding lag ranged from 5 to 14 months in the case of both total employment and employment of production workers. For employment of nonproduction workers, the estimated labor-hoarding lags ranged from 7 to 14 months. For the rectangular lag function, estimates of the labor-hoarding lag ranged from 3 to 15 months for total employment, 6 to 17 months for production workers, and 9 to 17 months for nonproduction workers. For the triangle, the corresponding ranges were 3 to 17 months for total employment, 4 to 16 months for production workers, and 1 to 20 months for nonproduction workers. Finally, for the geometric lag function, estimates of the labor-hoarding lag ranged from 2 to 15 months for total employment, 2 to 19 months for employment of production workers, and 9 to 22 months for employment of nonproduction workers.[11] Although there is not that much

from function to function since in some cases convergence was fast whereas in other cases it was slow. For the labor-hoarding lag, t*, the range was always 0 to 30 months. For the triangular lag function, five of the equations are not based on complete convergence of the variance about the estimated regression. In each of these five employment series, it was found that for large values of α_2 the estimated minimum cost employment series underestimated observed employment at the beginning of the samples for a number of months. Consequently, as α_2 was increased and the sample size reduced, the sums of squared residuals continued to decline. The estimates of the labor-hoarding lag, however, did not appear to be very sensitive in these series to increases in α_2 beyond 9 or 10 months. It was decided, therefore, to stop estimation at this point with the result that although the estimates of t* are fairly close to their maximum likelihood estimates, the estimates of the production lag probably contain some downward bias.

[11] It was found that the estimates of the parameters were not very sensitive to the choice of L_0 in the vicinity

[a] The critical value of $\chi^2(1)$ at the .05 significance level is 3.84.

difference in the range of estimates for the three employment classifications across functions, the estimates of the labor-hoarding lags for individual industries do appear to be quite sensitive to the specification of the distributed lag function. For example, in the case of employment of nonproduction workers in the metal working machinery industry, the estimates of t* ranged from 1 month in the case of the triangle to 22 months in the case of the geometric lag function. For blast furnaces and steel mills the estimates of the labor-hoarding lag for nonproduction workers ranged from 9 months in the case of the rectangle to 22 months in the case of the geometric lag function.

Table 2 contains the estimates of the additional parameters for each of the models. We can derive estimates of the production lag by adding 1 to the estimate of q in the case of the rectangle, and by multiplying α_2 by 2 in the case of the triangle. For the rectangle, the production lag estimates obtained from the three employment series did not vary much for the individual industries. For the triangle, there was a larger variation in the estimates. For example, in the case of industry 353, the estimated production lag from the nonproduction worker series was 4 months, from production workers 18 months, and from total employment 6 months. Finally, our results indicate that the production lag estimates, like the estimates of the labor-hoarding lags, are

of the beginning value of the observed employment series. For this reason L_0 was fixed at a value very close to the beginning value of the observed employment series.

fairly sensitive to the specification of the lag function.

We now ask whether our estimates of t*, for both the model without a production lag and the model with a production lag, provide strong enough evidence for rejecting the hypothesis that there is no labor hoarding (i.e., t*=0). A test of this hypothesis can be made by constructing the statistic:

$$Z = \frac{S_0^2 - S_1^2}{s} \tag{38}$$

which is asymptotically $\chi^2(1)$. The term S_0^2 is the sum of squared residuals under the null hypothesis that $t^*=0$; S_1^2 is the unconstrained sum of squared residuals; and s is an estimate of the variance around the regression from the unconstrained equation. The estimates of Z are given in Table 1. For the model without a production lag, the values of Z provide strong evidence for rejecting the null hypothesis at the 5 percent significance level in every equation. For the model with a production lag, in only three of the forty-five equations estimated are the values of Z such that we cannot reject the hypothesis of no labor hoarding.

The second hypothesis that we can test is the hypothesis that the production lag is not important in explaining the short-run demand for employment in the durable goods industries. A test of this hypothesis can be made by using the test statistic (Z) which will be distributed asymptotically as $\chi^2(1)$.[12] The term S_0^2 will now be the sum of squared residuals under the null hypothesis that there is no production lag; S_1^2 will be the sum of squared residuals from the unconstrained model which includes a production lag; and s is the estimate of the variance around the regression from the unconstrained equation. For the model with a production lag, the equation with the smallest variance adjusted for degrees of freedom was used in the test. Looking at Table 1, we can see that the geometric lag function performed best for all three employment series in the case of industries 331 and 354. The rectangular and triangular lag functions performed best for all three employment series for industry 351 and industry 361, respectively. For industry 353, the geometric lag function provided the best estimates in the case of total employment and employment of nonproduction workers but the rectangular lag function performed best in the case of production workers. The estimated values of Z given in Table 2 provide strong evidence for rejecting the null hypothesis at the 5 percent significance level in fourteen of the fifteen equations.

Finally, since we have estimated the employment model for total employment and its two components, employment of production workers and employment of nonproduction workers, it is possible to test the hypothesis that production workers and nonproduction workers are the same. This test can be made by computing the statistic:

$$V = \frac{S_{TE}^2 - (S_{PW}^2 + S_{NPW}^2)}{s_{PW} + s_{NPW}} \tag{39}$$

which is distributed asymptotically as $\chi^2(3)$ for the model without a production lag and $\chi^2(4)$ for the model with a production lag.[13] The term S_{TE}^2 is the sum of squared residuals from the total employ-

[12] If the production lag is not important, then this is equivalent to saying that $q=0$ in the case of the rectangle; that $\alpha_1=0$ in the case of the triangle; and, that $\alpha_2=0$ in the case of the geometric function.

[13] For the model with a production lag, we are assuming that there are four parameters identical: α_1, q, t*, and m in the case of the rectangle; α_1, α_2, t*, and m in the case of the triangle; and α_1, α_2, t*, and m in the case of the geometric lag function. For the model without a production lag, three parameters are assumed equal: α, m, and t*.

ment equation, representing the null-hypothesis that production workers and nonproduction workers are the same; S^2_{PW} and S^2_{NPW} are the sum of squared residuals from the unconstrained equations for production workers and nonproduction workers; and s_{PW} and s_{NPW} are estimates of the variances around the regressions from the unconstrained equations. The estimates of V are given in Table 3.

TABLE 3—TEST OF THE NULL HYPOTHESIS THAT PRODUCTION WORKERS AND NONPRODUCTION WORKERS ARE THE SAME

	No Production Lag	Assuming a Production Lag		
		V		
Industry	V	Rectangle	Triangle	Geometric
331	0	58	35	3
351	45	4	27	37
353	26	6	73	100
354	39	42	65	3
361	86	17	18	72

The critical values of $\chi^2(3)$ and $\chi^2(4)$ at the .05 significance level are 7.81 and 9.49, respectively.

In the case of the model without a production lag, the values of V for four of the five industries provide strong evidence for rejecting the hypothesis at the 5 percent significance level. For the model with a production lag, the null hypothesis is rejected in eleven of the fifteen equations.

IV. Summary and Conclusions

The purpose of this paper has been to construct a model of short-run employment behavior in durable goods manufacturing industries based on a theory of labor hoarding. This theory operates on the assumption that there are important costs associated with changing the labor force. Given these labor force adjustment costs, an optimal or minimum cost employment policy for a firm may be one in which the firm employs more labor during periods of declining output than is required to produce the desired level of output. Using the necessary and sufficient conditions for cost minimization, a programming algorithm was constructed which permitted us to obtain estimates of the maximum length of time it would be profitable for a firm to hoard idle workers, referred to as the labor-hoarding lag. Two models were constructed; the first model assumed that there was no production lag in durable goods industries, and the second model allowed for a production lag in the determination of required employment.

The results from both models provide strong evidence in support of the hypothesis that durable goods industries do hoard labor. Estimates of the labor-hoarding lag ranged from a low of 5 months to a high of 14 months in the case of the first model, and from a low of 1 month to a high of 22 months in the case of the second model. In addition, the performance of the second model in explaining the short-run behavior of employment in these industries was definitely superior to that of the first model. It was found, however, that the estimates of the labor-hoarding lag and production lag were fairly sensitive to the specification of the lag function.

Problems of Economic Policy from the Viewpoint of Optimal Control

By GREGORY C. CHOW*

A core problem in macro-economic policy is the evaluation of the performance of the economy under different specifications concerning the policy instruments. There are a number of interesting problems related to this core. The first is the setting of objectives in terms of which the performance can be evaluated. Second, given our knowledge of the economy, do policies exist that will serve to achieve or closely achieve these objectives? Third, how are good policies to be found and what form should they take? Presumably, a policy may involve coordinated use of several instruments. Fourth, assuming that our competing objectives, such as full employment and price stability, cannot be met perfectly by the best of policies, by how much can we improve upon the attainment of one objective by sacrificing the attainment of another? This is the problem of measuring the tradeoff possibilities available to the policy maker. Fifth, how are different policy proposals to be ranked and compared? Sixth, how can historical policies be appraised? Seventh, if one had to choose between subsets of instruments, say between monetary and fiscal instruments, in what way could a choice be made? In other words, how can the effectiveness of a subset of instruments be measured, relative to that of another subset?

In this paper, I hope to demonstrate that these problems can, and indeed should, be studied by the tools of optimal control for stochastic systems in economics. The above problems are by no means exhaustive, but they will be sufficient for illustrative purposes. In fact, the list may already be too long to be thoroughly treated in one paper. Fortunately for my exposition, a recent article by Robert Holbrook on "Optimal Economic Policy and the Problem of Instrument Instability" has raised several issues that are related to the first four problems listed in the preceding paragraph. I will use the topic of instrument instability as a starting and focal point of my discourse on the first four problems, leaving the remaining problems to be discussed later in this paper. I will show that the questions raised, and only partially studied, by Holbrook, as well as the other questions concerning optimal economic policy, can be answered by the techniques of optimal control in a fairly general setting.

Instrument instability was said to exist by Holbrook if "attempts to offset completely the cumulative impact of past changes in the policy instrument may require ever greater changes in the future value of the instrument" (p. 57). An example is provided by the model

$$y_t = .4x_t + .6x_{t-1} + 10$$

where y_t is the endogenous variable to be controlled and x_t is the instrument. If the objective is to make $y_t = 10$, for many future periods, the solution is to set $.4x_t + .6x_{t-1} = 0$, or $x_t = -1.5x_{t-1}$, a situation characterized as one of instrument instability.

* Princeton University. I would like to acknowledge, with thanks, helpful comments from George Borts, and financial support from the National Science Foundation through Grant NSF GS 32003X.

It is not difficult to see that the questions of instrument instability are related to the first four problems listed above. To study these problems in a more general setting than Holbrook, let there be given a linear econometric model in its reduced form,

$$(1) \quad y_t = A_1 y_{t-1} + \ldots + A_m y_{t-m} + C_0 x_t + \ldots + C_n x_{t-n} + b_t + u_t$$

where y_t is a vector of endogenous variables, x_t is a vector of instruments, A_i and C_i are given constant matrices, b_t are given vectors capturing the combined effects of other exogenous variables which are not subject to control, and u_t is a random vector with mean 0, covariance matrix V, and is uncorrelated with $u_s(t \neq s)$. One may ask, under what conditions will instrument instability exist? This question requires a definition of "instability," which involves the setting of objectives for the performance of the economy. Given some definition of stability as an objective, it is concerned with the possible nonexistence of a policy that will serve to achieve the desired objective. Secondly, one may ask, if instrument instability is found to exist, to what extent and in what way can the policy maker trade off this instability by allowing for instability in the endogenous variable(s) to be controlled? This question involves finding a good solution to reduce instrument instability, and ascertaining the tradeoff between instabilities in the instrument(s) and in the endogenous variable(s). Third, if one instrument, say federal expenditures, is found to be unstable when it is regarded as the only instrument (holding as fixed another instrument such as money supply), to what extent will the availability of another instrument alleviate the problem of instrument instability? This obviously involves the tradeoff between instabilities in different instruments. This question, which was not raised by Holbrook because his framework only allowed him to study one instrument at a time, will simply be treated by our method as a special case of the second question.

Our framework will be more general than Holbrook's in (a) having possibly more than one endogenous variable to be controlled, (b) having possibly more than one instrument to be studied, (c) having possibly unequal numbers of endogenous variables and instruments, and (d) having possibly random disturbances in the system. Furthermore, our solution can be generalized to the case of (e) treating the matrices A_i and C_i as random matrices when the policy maker is uncertain about their values, and (f) of non-linear dynamic models. This paper will deal only with generalizations (a), (b), (c), and (d), leaving (e) and (f) to appropriate references. All the questions raised so far can be analyzed fairly easily once a framework of optimal control is set forth. This is the immediate task of Section I. In Section II, the results of this framework will be used to study problems associated with instrument instability. In Section III, modifications due to the stochastic nature of the problem will be set forth. Section IV deals with the other problems of economic policy mentioned above.

I. A Framework of Optimal Control

Let us begin by rewriting the dynamic system (1) as a first-order system (2) in which the "current endogenous variables" will incorporate the instruments. We shall redesignate system (2) simply as equation (3).

$$(3) \quad y_t = A y_{t-1} + C x_t + b_t + u_t$$

Note that the newly defined y_t includes current and (possibly) lagged endogenous variables as well as current and (possibly) lagged instruments, whereas x_t remains the same as before. This rewriting serves

$$(2)\quad \begin{bmatrix} y_t \\ \cdot \\ \cdot \\ y_{t-m+1} \\ x_t \\ \cdot \\ \cdot \\ x_{t-n+1} \end{bmatrix} = \begin{bmatrix} A_1 \dots A_m & C_1 \dots C_n \\ & \\ \dots I \quad 0 & 0 \dots 0 \\ 0 \dots 0 & 0 \dots 0 \\ & \\ 0 \dots 0 & \dots I \quad 0 \end{bmatrix} \begin{bmatrix} y_{t-1} \\ \cdot \\ \cdot \\ y_{t-m} \\ x_{t-1} \\ \cdot \\ \cdot \\ x_{t-n} \end{bmatrix} + \begin{bmatrix} C_0 \\ \cdot \\ \cdot \\ 0 \\ I \\ \cdot \\ \cdot \\ 0 \end{bmatrix} x_t + \begin{bmatrix} b_t \\ \cdot \\ \cdot \\ 0 \\ 0 \\ \cdot \\ \cdot \\ 0 \end{bmatrix} + \begin{bmatrix} u_t \\ \cdot \\ \cdot \\ 0 \\ 0 \\ \cdot \\ \cdot \\ 0 \end{bmatrix}$$

two main purposes. First, by incorporating the instruments in y_t, we can evaluate the performance of the economic system by the behavior of y_t alone even when the behavior of some instruments, such as government expenditures, should be included. This will simplify the writing of the objective function. Second, as is well known, the reduction of a higher order system into first order also facilitates exposition.

The performance of the system for a finite planning horizon from period 1 to period T will be judged by the deviations of y_t, as defined in (3), from the vectors a_t which are targets to be specified by the policy maker ($t=1, \dots, T$). Specifically, welfare cost will be measured by

$$(4)\quad W = E_0 \sum_{t=1}^{T} (y_t - a_t)' K_t (y_t - a_t)$$

where E_0 denotes expectation conditional on the initial condition y_0, again in the notation of (3), the prime denotes transpose, and K_t are known, symmetric (usually diagonal), positive semidefinite matrices, with zero elements as a rule corresponding to lagged (endogenous and control) variables. The problem is to minimize expected welfare cost (4) by setting the time path of the instrument $x_t(t=1, \dots, T)$, given the model (3).

The formulation of this problem is dynamic. The performance criterion evaluates y_t for many periods. Since the decision x_1 for the first period will affect the outcomes y_t for later periods through the system (3), thus restricting the possibilities open in later periods, one should take into account the multiperiod character of this problem in choosing (and hence also in appraising) the values of the instruments at each period. The problem is also stochastic. One cannot control the future outcomes exactly, but only the probability distributions of the outcomes and the expectation of certain (welfare) functions of these outcomes. It is concerned with the evaluation of stochastic time-series y_t under different regimes. The stochastic nature has implications on comparing different policy proposals and on judging historical policies.

Because the model is linear, its parameters are assumed to be known, and because the welfare cost is quadratic, the dynamic stochastic problem here formulated is one of the simplest and most basic problems in stochastic control theory. While other elementary methods of solving this problem can be found in Chow (1972a, b), I will provide here a solution using the method of dynamic programming of Richard Bellman. The method begins by solving the problem for the last period T, given the initial condition y_{T-1}. The welfare cost is

$$(5)\quad \begin{aligned} W_T &= E_{T-1}(y_T - a_T)' K_T (y_T - a_T) \\ &= E_{T-1}[y_T' H_T y_T - 2y_T' h_T + c_T] \end{aligned}$$

where we have set $H_T = K_T$ for ease of generalization to the multiperiod problem later on, and have set $h_T = k_T = K_T a_T$, and $c_T = a_T' K_T a_T$. Using the model (3) for y_T

and taking expectations, we minimize

$$(6)\quad W_T = (Ay_{T-1} + Cx_T + b_T)'H_T(Ay_{T-1} + Cx_T + b_T) - 2(Ay_{T-1} + Cx_T + b_T)'h_T + E_{T-1}u_T'H_Tu_T + c_T$$

by differentiating with respect to the vector x_T,

$$(7)\quad \frac{\partial W_T}{\partial x_T} = 2C'H_T(Ay_{T-1} + Cx_T + b_T) - 2C'h_T = 0$$

The solution of (7) yields the optimal policy for the last period,

$$(8)\quad \hat{x}_T = G_Ty_{T-1} + g_T$$

where

$$(9)\quad G_T = -(C'H_TC)^{-1}(C'H_TA)$$

$$(10)\quad g_T = -(C'H_TC)^{-1}C'(H_Tb_T - h_T)$$

Equation (8) is the optimal feedback control equation, showing that the optimal policy for period T is a linear function of all the variables y_{T-1} which will affect the outcome y_T through system (3). It also shows the multiperiod nature of our solution. The value of $\hat{x}_T$ cannot be set in period 1 since it depends on y_{T-1} which is not yet observed, but the optimal $\hat{x}_T$ can be specified as a function of y_{T-1}, and this function will be needed for us to determine the optimal policies for earlier periods.

To obtain the optimal expected cost for the last period, conditional on the data y_{T-1}, we substitute (8) for x_T in (6),

$$(11)\quad \hat{W}_T = y_{T-1}'(A+CG_T)'H_T(A+CG_T)y_{T-1} + 2y_{T-1}'(A+CG_T)'(H_Tb_T - h_T) + (Cg_T+b_T)'H_T(Cg_T+b_T) - 2(Cg_T+b_T)'h_T + c_T + Eu_T'H_Tu_T$$

Consider now the problem for one more period T−1. This two-period problem involves the choice of two policies, x_T and x_{T-1}, but we have already found an optimal policy $\hat{x}_T$ for the last period as a function y_{T-1}. The only remaining problem is to choose x_{T-1} optimally. The choice of x_{T-1} will affect y_{T-1}, but, whatever y_{T-1} will be, our previous solution guarantees that x_T shall be chosen optimally. This logic carries over to many periods. At the beginning of any period t, we are concerned only with the choice of x_t provided that we have obtained the optimal solution for the remaining periods from t+1 on. That solution will depend on y_t which the current decision x_t will influence, but whatever the outcome y_t may be, we know that all future decisions $x_{t+1}, \ldots, x_T$ will be optimally chosen. By the principle of optimality of Bellman, we minimize only with respect to x_{T-1}

$$(12)\quad E_{T-2}[y_{T-1}'K_{T-1}y_{T-1} - 2y_{T-1}'k_{T-1} + a_{T-1}'K_{T-1}a_{T-1} + \hat{W}_T]$$

where the welfare cost includes the contribution from the current period T−1 plus the optimal cost from period T on. Substituting (11) for $\hat{W}_T$ into (12) will yield

$$(13)\quad W_{T-1} = E_{T-2}[y_{T-1}'H_{T-1}y_{T-1} - 2y_{T-1}'h_{T-1} + c_{T-1}]$$

where

$$(14)\quad H_{T-1} = K_{T-1} + (A+CG_T)'H_T(A+CG_T)$$

$$(15)\quad h_{T-1} = k_{T-1} + (A+CG_T)'(h_T - H_Tb_T)$$

$$(16)\quad c_{T-1} = a_{T-1}'K_{T-1}a_{T-1} + (Cg_T+b_T)'H_T(Cg_T+b_T) - 2(Cg_T+b_T)'h_T + c_T + Eu_T'H_Tu_T$$

The solution for the T-period problem is complete if one observes that the expression (13) to be minimized with respect to x_{T-1} has the same form as expression (5). One can thus repeat the process from

equations (5) to (16), with the subscript T replaced by T−1, and so forth. In summary, optimal control consists of choosing the instrument x_t as a linear function $G_t y_{t-1}+g_t$ of the variables y_{t-1} of the previous period, as in equation (8). The matrices of coefficients G_t are determined, together with H_t, by solving equations (9) and (14) alternatively, backward in time from t=T, and with initial condition $H_T=K_T$. The matrices G_t and H_t having been obtained, the vectors g_t, together with h_t, are determined by solving equations (10) and (15) alternatively, backward in time from t=T, and with initial condition $h_T=k_T\equiv K_T a_T$.

Of course, in the beginning of period 1, one needs to act only on x_1, but the above derivation shows that the optimal $\hat{x}_1$ depends on G_1 and H_1, which in turn depend on the future H_t and G_t, t=2, . . . , T. By the multiperiod nature of our problem, future policies have to be taken into account in the determination of the optimal policy for the first period. Our calculations will also yield the expected welfare cost associated with the optimal policy from periods 1 to T, given the initial condition y_0. It is given by equation (11), with T replaced by 1, thus being a quadratic function of y_0. In the calculation of $\hat{W}_1$, we need c_1, which can be obtained by solving equation (16) backward in time.

If the matrices K_t in the welfare function are all equal to K, the solution for G_t and H_t may reach a steady state, for t smaller than a certain value, that will satisfy

$$G = -(C'HC)^{-1}C'HA; \tag{17}$$

$$H = K + (A + CG)'H(A + CG) \tag{18}$$

Since (18) can be written as an infinite series

$$H = K + (A + CG)'K(A + CG) + (A + CG)'^2K(A + CG)^2 + \dots \tag{19}$$

the steady state will exist if, and only if, the series converges. Convergence occurs if all the characteristic roots of the matrix $(A+CG)$ are smaller than one in absolute value. Even when G_t and H_t do reach a steady state, g_t and h_t will usually not do so if $k_{t-1}(\equiv Ka_{t-1})$ and b_t are changing through time, as can be seen from equation (15). If G_t is constant for t=1, 2, 3, . . . , the optimal policies $\hat{x}_t$ should respond to the data y_{t-1} in the same way, but the intercepts g_t will change because the targets a_t and the effects b_t of the uncontrolled exogenous variables are changing—optimal policies should take these changes into account.

II. Problems Associated with Instrument Instability for Deterministic Systems

The questions raised by Holbrook are for a deterministic model, i.e., model (1) with $u_t=0$. It may be of interest to consider this special case first. Note that the above formulation of, and solution to, the optimal control problem applies easily to this case—simply erase the expectation signs and set u_t equal to zero. The linear feedback control equations $x_t=G_t y_{t-1}+g_t$ and the computations of G_t and g_t remain the same as in the stochastic case.

Before analyzing any questions, one may wish to define instrument instability. Holbrook did not give a precise definition. By this term, one might mean (a) that the optimal time paths of x_t are explosive and/or (b) that they contain oscillations. If x_t satisfies a system of linear difference equations, (a) will occur when some roots of the system are larger than unity in absolute value; (b) can occur if some roots are complex and/or negative.[1] I suppose that the degrees of (a) and (b), namely, how explosive and how large the oscillations, should also matter. Thus the

[1] Proofs of these well-known propositions can be found in Chow (1968).

absolute values of the roots, be they real or complex, will matter. If one specifies that the first differences of economic variables satisfy a linear model like (1), he might reasonably require, in his definition of stability, that the instruments x_t (also in first differences) be not explosive, or not very explosive. But if the model explains the levels of economic variables which are expected to grow, some explosiveness in the instruments should not be considered unstable. In short, instrument instability requires one to examine the explosiveness and/or the extent of oscillations of the optimal time paths of the instruments x_t.

Will instrument instability exist for a particular system? To answer this question, one simply studies the optimal path of x_t, which, in the notation of (3), is imbedded in the vector y_t. When optimally controlled, y_t will satisfy (in the deterministic case)

$$(20)\quad \begin{aligned} y_t &= Ay_{t-1} + Cx_t + b_t \\ &= (A + CG_t)y_{t-1} + b_t + Cg_t \end{aligned}$$

and the behavior of such a system can easily be analyzed, especially when G_t reaches the steady state G. For $G_t=G$, and denoting b_t+Gg_t by $\bar{b}_t$, say, the solution to (20) is

$$(21)\quad \begin{aligned} y_t = (A + CG)^t y_0 &+ \bar{b}_t \\ &+ (A + CG)\bar{b}_{t-1} + \dots \\ &+ (A + CG)^{t-1}\bar{b}_1 \end{aligned}$$

in which the homogeneous part $(A+CG)^t y_0$ is explosive or oscillatory, depending on whether the roots are large in absolute value or complex.

One might ask, if the system omitting the influence of x_t, i.e.,

$$(22)\qquad y_t = Ay_{t-1} + b_t$$

is explosive (damped), will the system including the instruments x_t which are set optimally, i.e., system (20), be explosive (damped) also? Either case can happen, but to dampen an otherwise explosive system by optimal control is more likely than to change an otherwise stable system to an explosive one. After all, a purpose of control may be to dampen an explosive system. From equation (9) for G_t (or from equation (17) for G), each column of the optimal feedback control matrix G_t can be interpreted as coefficients of a regression of the corresponding column of the matrix A on columns of the matrix $-C$. In other words, if the first column of A, say A_1, are observations on a dependent variable, and the columns of $-C$ are observations on the explanatory variables, then the first column of G_t, say $G_{t,1}=-(C'H_tC)^{-1}C'H_tA_1$, are coefficients in the regression $A_1 = -CG_{t,1}+R_{t,1}$ obtained by the method of Aitken's generalized least squares. The purpose of regression is to make the columns of residuals

$$(R_{t,1}R_{t,2}\dots) = R_t = A + CG_t$$

small—in fact, for column 1, it is to minimize the weighted sum of squares of the residuals $R'_{t,1}H_tR_{t,1}$. Therefore, if some roots of A are larger than one in absolute value, the roots of the matrix $R_t=A+CG_t$ of regression residuals may not be, in which case the system under control is damped.

How would it be possible for the matrix A to be stable, but the matrix $A+CG$ (omitting subscript t) to be unstable? It is possible, when the weighting matrix H, which is derived from the matrix K of welfare weights by equation (14), is uneven in assigning weights to different residuals. As an example, consider the simple system given in the third paragraph of the introduction of this paper. In the notation of (2) and (3), this system is

$$\begin{bmatrix} y_t \\ x_t \end{bmatrix} = \begin{bmatrix} 0 & .6 \\ 0 & 0 \end{bmatrix}\begin{bmatrix} y_{t-1} \\ x_{t-1} \end{bmatrix} + \begin{bmatrix} .4 \\ 1 \end{bmatrix} x_t + \begin{bmatrix} 10 \\ 0 \end{bmatrix}$$

The matrix A has multiple roots of zero. If the purpose of control is to steer y_t to target, but to ignore the behavior of x_t, the 2x2 matrix K is diagonal with unity as its leading element, and

$$(23) \quad G_T = -\left[(.4 \quad 1)\begin{pmatrix}1 & 0\\0 & 0\end{pmatrix}\begin{pmatrix}.4\\1\end{pmatrix}\right]^{-1} \cdot (.4 \quad 1)\begin{pmatrix}1 & 0\\0 & 0\end{pmatrix}\begin{pmatrix}0 & .6\\0 & 0\end{pmatrix} = -(.16)^{-1}(0 \quad .24) = (0 \quad -1.5)$$

$$(24) \quad A + CG_t = \begin{pmatrix}0 & .6\\0 & 0\end{pmatrix} + \begin{pmatrix}0 & -.6\\0 & -1.5\end{pmatrix} = \begin{pmatrix}0 & 0\\0 & -1.5\end{pmatrix}$$

$$(25) \quad H_{T-1} = K + (A + CG_T)'K(A + CG_T) = K = \begin{pmatrix}1 & 0\\0 & 0\end{pmatrix}$$

Therefore, the values for G_T and H_{T-1} given in (23) and (25) are steady-state values, and we have an explosive root -1.5 in the residual matrix $A+CG_T$.

One can now state several relevant propositions concerning optimal control that are based on the theory of Section I. First, it is possible to steer certain endogenous variable(s) exactly to targets, under appropriate conditions to be specified below, by solving the optimization problem of Section I that employs the quadratic welfare function (4), and assigning positive costs only to the deviations of the variable(s) selected. Second, if the number of target variables (the number of nonzero diagonal elements in K) is equal to the number of instruments, the minimization problem of equation (5) will be solved with $(y_T - a_T)'K(y_T - a_T) = 0$, and so on for equation (13), etc., and the variables will be on target exactly—assuming that the rank of C is equal to the above number. Third, if the number of target variables is larger than the number of instruments, the former variables will not reach targets exactly, and their deviations from targets will depend on the welfare weights in K assigned to them.[2]

Fourth, instrument instability, insofar as it pertains to some characteristic of the time path x_t, can exist no matter whether the welfare weights are assigned only to the originally endogenous variables, or also to the instruments (imbedded in y_t). Holbrook treated only the former case, in fact, a rather special case of the former when the numbers of target variables and of instruments are both equal to one. Fifth, once the last point is recognized, as it is from the theory of Section I, one can trade off the stability characteristics not only between the truly endogenous variables and the instruments, but also among the instruments themselves (and among the endogenous variables themselves, of course). All these can be accomplished by changing the diagonal elements of the matrix K. For example, if total government expenditures and money supply are two instruments, giving more weight to the former (and specifying its target path to be smooth) will mean more stability for it, as compared with the latter instrument, when the weights for the endogenous variables remain unchanged.

Once the basic ideas of optimal control are understood, one might not wish to take the concept of instrument instability very seriously. What matters are the dynamic characteristics of the time path in question, be it a dependent variable or an instrument. Moreover, within the framework of Section I, a good measure of the dynamic performance of the variable is the sum of its squared deviations from the target path over time. If the variable fluctuates violently, and the target path is

[2] If the number of target variables is smaller than the number of instruments, there will be more than one way to achieve the targets exactly, and the computation of the optimal control matrices G_t can be performed by using a generalized inverse for $(C'H_tC)$, where the rank of H_t and thus of the entire matrix, is smaller than the number of instruments.

smooth, its performance is poor by this measure. If the variable increases rapidly, and the target calls for no increase or a small increase per period, its performance is poor by this measure. Having solved the problem of optimal control, one can easily compute the optimal path of y_t (including x_t as a subvector) using equation (20) and thus the sums of squared deviations of all variables from targets, and, in fact, a weighted sum of these sums as a measure of welfare cost.

Having discussed instrument instability, we have also provided answers to the problems of setting objectives, ascertaining the existence of good solutions (by simply calculating $\hat{W}_1$), finding optimal solutions, and, to a lesser extent, welfare tradeoffs between target variables, possibly including instruments. The last problem and the remaining problems mentioned in the introduction will be treated in Section IV. In the next section, modifications required by the stochastic nature of the problem will be discussed.

III. Modifications for Stochastic Systems

For a stochastic system, one retains the random disturbance u_t in equation (3) and the expectation sign in equation (5), etc. The objective of control, in the framework of Section I, is to minimize the expectation of a weighted sum of squared deviations of selected variables from targets. In this section we will point out several implications of including the random disturbance in the dynamic system (3).

First to be noted is the fact that the optimal control equations $\hat{x}_t=G_t y_{t-1}+g_t$ remain exactly the same as in the deterministic case. However, there is an important difference in that the time path of the optimal $\hat{x}_t$ is now stochastic, since y_{t-1} is stochastic, whereas both $\hat{x}_t$ and y_{t-1} were deterministic before. In other words, when $u_t=0$, it was possible to calculate, in period 1, the optimal $\hat{x}_t$ for all t, since all future y_t were to be determined by equation (21). With stochastic disturbances present, future y_t becomes stochastic, and optimal $\hat{x}_t$ can be determined numerically only after y_{t-1} are observed.

It is fruitful to decompose the stochastic time series y_t generated by the system (3), when x_t is optimally controlled, into two parts. The first part $\bar{y}_t$ is deterministic and the second y_t^* is stochastic. When x_t follows the optimal policy $\hat{x}_t=G_t y_{t-1}+g_t$, system (3) will become, with G_t reaching the steady state G, and with $\bar{b}_t$ denoting b_t+Cg_t:

$$(26)\qquad \begin{aligned} y_t &= (A+CG)y_{t-1}+\bar{b}_t+u_t \\ &= Ry_{t-1}+\bar{b}_t+u_t \end{aligned}$$

After repeated substitutions of y_{t-1} in (26) by $Ry_{t-2}+\bar{b}_{t-1}+u_{t-1}$, and y_{t-2} by $Ry_{t-3}+\ldots$, etc., one easily finds that

$$(27)\qquad \begin{aligned} y_t = R^t y_0 &+ (\bar{b}_t+R\bar{b}_{t-1}+\ldots+R^{t-1}\bar{b}_1) \\ &+ u_t+Ru_{t-1}+\ldots+R^{t-1}u_1 \end{aligned}$$

The first line on the right-hand side of (27) is the mean of the process, to be denoted by $\bar{y}_t$. It is identical with the time path (21) of the deterministic system of Section II, with $\bar{y}_0=y_0$. The second line of (27) is the deviation from mean, or the random part of the process, to be denoted by y_t^*. It is generated by the process

$$(28)\qquad y_t^* = Ry_{t-1}^* + u_t$$

If one were interested in studying instrument instability for this dynamic stochastic system under control, he would have to define "instability" in terms of certain dynamic characteristics of a stochastic time-series, and to ascertain these characteristics for the time series y_t given by (27). Once y_t is decomposed into $\bar{y}_t$ and y_t^*, there are ways to characterize its explosiveness and cyclical fluctuations, and to derive the measures of these characteris-

tics for system (27).[3] We will not pursue the subject in this paper because instrument instability is not considered to be a subject of great interest in itself and because an adequate treatment would be too lengthy here.[4]

As it was pointed out in Section II, instrument instability should be taken less seriously than, or should be replaced by, the weighted sum of squares of deviations of y_t from the targets a_t, where y_t incorporate both instruments and truly endogenous variables. In the stochastic case, it is the expected weighted sum of squares given by (4) for any policy, or by $\hat{W}_1$ for the optimal policy. Equation (11) for $T=1$ and equation (16) can be used to compute $\hat{W}_1$ for the stochastic case. Note that, in the deterministic case, all $Eu_t'H_tu_t$ in the calculation of $\hat{W}_1$ would be zero. Thus the (optimal) expected welfare loss in the stochastic case equals the loss for the deterministic case, i.e., for the time-series $\bar{y}_t$, plus the expected loss due to the random disturbances, i.e., from the time-series y_t^* of equation (28). The former component is due to deviations of $\bar{y}_t$ from a_t, while the latter component is due to the deviations of y_t from $\bar{y}_t$, namely, the deviations y_t^*.[5] This decomposition deserves several comments. First, even if the number of instruments equals the number of target variables, one cannot expect the stochastic time-series y_t to be on target exactly because of random disturbances, and the expected squared deviations will contribute to the expected welfare loss, as measured by the second component of $\hat{W}_1$—here the first component is zero because the deterministic path $\bar{y}_t$ is exactly on target. Second, when the number of target variables exceeds the number of instruments, as it is more often the case, both components of $\hat{W}_1$ will be positive. Third, calculations based on the simple, aggregative macro-economic model of Chow (1967) have shown that, for a number of reasonable welfare functions, the component of $\hat{W}_1$ due to the stochastic disturbances is invariably much larger than the deterministic component, indicating the importance of considering the stochastic aspect of the problem in the measurement of welfare cost.[6] Thus, although the introduction of random disturbances does not change the optimal control equations, it materially affects the nature of the time series generated by the controlled system, and increases the optimal expected welfare cost.

Perhaps it is felt that recognizing the random disturbances is to recognize only a part of the problems associated with a stochastic system. Another important aspect is the uncertainty of the exact values of the parameters A and C of the system (3). When A and C are estimated statistically, the errors in the estimates have to be taken into account in the design of optimal policies, as they would affect both the optimal control equations and the associated expected welfare loss. This subject is treated in Chow (1972c) and will not be pursued further here. For an approach to control problems with non-linear systems, the reader is referred to Michael Athans.

IV. Other Problems of Economic Policy

First, let us consider the problem of ascertaining the tradeoff possibilities between different target variables. The optimal control solution will minimize the welfare loss by appropriately weighting the respective sums of squares of deviations of these variables from targets ac-

[3] These have been developed and discussed at length in Chow (1968), (1970), Chow and Richard Levitan (1969a, b).

[4] The treatment would be straightforward by methods set forth in the references cited in the preceding footnote.

[5] For alternative developments of this decomposition, see Chow (1972a, b).

[6] These calculations can be found in Chow (1972b).

cording to the elements of the matrix K. In the deterministic case, the solution provides a given value for each target variable for each time period. In the stochastic case, the mean values of the target variables are given by $\bar{y}_t$, as well as their variances and covariances by the variances and covariances of y_t^*. Thus, the sum of squared deviations over time of each variable from its target path, or the expectation thereof in the stochastic case, is provided by the optimal solution. For example, the average squared deviation over time for the rate of unemployment (from zero) may turn out to be the square of 6 percentage points, and the average squared deviation for the rate of inflation (from zero) may be the square of 4 percent per year. To obtain another point in the unemployment-inflation tradeoff, say with a reduction of unemployment, one simply changes the diagonal elements of the matrix K to make the deviation of unemployment more costly relative to that of inflation, and calculates another optimal solution. The latter may turn out to be a combination of 5 percent unemployment and 5 percent inflation.

There appear to be advantages of this approach for ascertaining the tradeoff possibilities between different objectives over the approach by simulations as it is currently practiced. First, we are forced, in the optimal control framework, to make some attempt to rank the different sets of time paths for the target variables to be generated by different policies. Second, the ranking is done not only for one sample from each policy but for the average over samples as derived analytically by taking mathematical expectation. Often, simulation studies ignore the stochastic disturbances in the system. If they do not, averaging over many samples generated by random drawings from the distribution of the disturbances will be required, and the errors in estimating the true mathematical expectation of the squared deviations are often difficult to assess. Furthermore, and this is the third point, without doing some optimization as a guide, one would have to try many different policies in a simulation study. This not only aggravates the difficulties of the second point, but more importantly, one may never discover the very good policies. From the viewpoint of tradeoffs, one may miss the policies that would lower both the rates of unemployment and inflation.

A purist may object to the method of ascertaining the tradeoffs as described above. If one were to take his quadratic welfare function seriously, and obtain an optimal solution with 6 percent unemployment and 4 percent inflation for some year, this must be the best that he can do. There is no reason for exploring whether a combination of 5 percent and 5 percent is feasible, because, even if it were, the policy maker would not prefer it as it is not optimal according to his solution. There are at least two answers to this. First, another policy maker may have a different welfare function, and may prefer a 5-5 combination to a 6-4, and it would be useful to exhibit various possibilities. Second, a quadratic welfare function has many well-known limitations. It may be a reasonable approximation to the preference of the policy maker only in a certain region of the target-variable space, say near the target point a_t of (3, 2) for unemployment and inflation and to the right and above that point. If the optimal solution is far from that region, the policy maker will want to write another quadratic approximation to his preferences to see whether the result will turn out to be better. This will amount to the procedure which we have recommended, with the amendment that the target point itself is subject to change, besides the matrix K.

Another problem of interest is the evaluation of policy proposals. For ex-

ample, would increasing money supply by 5 percent per year be a good policy? Such a proposal is not a complete specification of a policy. What are to be assumed for the other instruments? Are they to follow an optimal feedback rule while money supply is to be increased at a constant rate, or are they to maintain constant rates of change also? In the latter case, at what rates? By what criteria is the dynamic performance of the economy to be judged? Using the framework of optimal control, I have specified target paths for certain econlmic variables generated by the model of Chow (1967) and obtained the suboptimal policies under the restriction that the two instruments, money supply and government expenditures, are to grow at constant rates—the rates being determined suboptimally for each welfare function specified. I have then compared the welfare losses associated with these policies with those for the optimal policies, and have found that the former are from 40 to 80 percent larger than the latter for the given econometric model. The results are reported in Chow (1972b), and they constitute an evaluation of policy proposals by the method of optimal control.

For both the evaluation of policy proposals and the appraisal of historical policies, it is necessary to use a dynamic model in order to take into account the effects of a decision in one period on the outcomes of later periods. It is also necessary to treat the decision of one period in conjunction with the decisions of other periods. It would be inadequate to evaluate an action solely by the consequence in the same period, or to ignore the structure of intertemporal decisions.[7] The desirability of using a welfare function as a yardstick and of using an optimal control solution as an alternative for comparison require no further comment here. Furthermore, for the appraisal of historical record, it would be desirable to describe the behavior of policy makers by some decision rule, rather than by the numerical outcomes of their actions. This suggestion is entirely consistent with the recent research interest in explaining government policy variables by systems of equations. These equations are useful for forecasting purposes, and the explanation of government behavior quantitatively is in itself important. For the purpose of historical appraisal, this suggestion is consistent with the fundamental proposition in the study of decision under uncertainty that a decision should be judged by the expected utility of the outcome when it is made, and not by the utility of the outcome that actually occurs since the latter is affected by chance elements. In a deterministic world, one could use a nonstochastic economic model, and compare the time paths of the economic variables generated by the historical values of the instruments, treated as constants, and the time paths generated by alternative values of the instruments, also treated as constants. When there are random disturbances, the historical values might be sample outcomes of certain rules and should not be judged as if the policy makers had specified these quantities as constants independent of the random events that had occurred. By incorporating empirically estimated dynamic relationships describing government policies into an econometric system, as we did for the optimal policies, one can study the dynamic performance of the

[7] Without the benefits of the tools of optimal control, early studies in the evaluation of macro-economic policies ran into these difficulties. For example, Martin Bronfenbrenner, in comparing rival monetary rules, assumed that the effect of a change in money supply would work out in the period of one year. The study of Franco Modigliani, in comparing for each period the historical money supply with some "target" money supply which the author specified, also failed to consider the dynamic consequences of a decision. Furthermore, the target money supply could hardly have been an optimal path since intertemporal decision was not considered.

economy as it was historically regulated. Comparison of the expected welfare loss and other properties, with those of an optimal policy, or of an alternative policy proposal, can then be made. A crude beginning based on this approach was described in Chow (1972b).

As the last problem, consider the measurement of the effectiveness of monetary versus fiscal policies. It is generally recognized that comparing the coefficients of money supply and government expenditures in a regression of national income on these variables will leave many questions unanswered. Is national income the only variable of interest? How can coefficients be compared without giving considerations to the costliness of changing the policy variables? How about the dynamic nature of the problem? The lagged effects of the instruments will have to be judged, but not by simply inspecting the sets of coefficients in a distributed-lag relationship between national income and the instruments, because a relevant comparison requires letting each set of policy instruments perform at its best under a dynamic and stochastic setting, namely, letting them follow some optimal control rules. This last point applies equally well to the study of effectiveness of different policy instruments by the method of simulations using dynamic econometric models. Not only is the estimation of expected welfare associated with each policy by way of stochastic simulations involving many variables for many periods costly and subject to errors, as pointed out before, but it is virtually impossible to design rules for these instruments which will show their true "effectiveness" without some optimization procedure as described in this paper.

I hope to have demonstrated that the concepts and tools of this paper are extremely useful and important for the study of economic policy, and that this subject can be greatly advanced by an approach that is fundamentally multivariate, dynamic, forward-looking, and stochastic in conception. The theory of macro-economic policy need no longer be built on comparative statics under the assumption of certainty, but rather should be concerned with problems of comparative dynamics in a stochastic setting.[8] In the empirical study of economic policy, the tools of optimal control should not be regarded as capable of yielding one final solution to policy, but rather should be applied with flexibility as a means of uncovering the preferences of decision makers, the reasonably good possibilities open for policy, and thus the dynamic characteristics of the economy.

The Interaction Between Federal Credit Programs and the Impact on the Allocation of Credit

By Rudolph G. Penner and William L. Silber*

Federal credit programs and policies aimed at increasing the amount of resources devoted to specific types of "socially desirable" expenditures, such as housing, have expanded considerably during the past five years. In general, these policies and specific programs have costs. They also interact with one another in an, as yet, undefined way. Our objectives in this paper are to describe the determinants of the relative effectiveness of the different government credit programs and policies in implementing the flow of funds (and resources) into a particular sector. We also analyze the interaction between different credit programs. Housing will be used as the specific example because it is currently high on the priority list of government policy and, more importantly, there are a myriad of policies and programs aimed at promoting housing.

Three qualifications are in order at this point. We include in the term "costs" the total *direct* cost to the government and private sector arising from a particular policy. We do not compare the indirect costs of a program such as the possible reduction in the efficiency of the financial sector or any excess burdens of a policy in the welfare sense. We also do not question the government's concern with housing. The government intervenes and subsidizes a sector of the economy when it believes that real social benefits exceed private benefits or real social costs are less then the private sector's evaluation of real costs. We assume this to be the case in housing. Finally, we do not analyze the costs and benefits of diverting the flow of resources via credit programs as opposed to attaching subsidies to the real side of, say, housing activity. Most government housing programs are aimed at diverting the flow of credit. Our concern is with the interaction between and impacts of these programs.

In Section I of the paper we provide the conceptual and analytic framework. In Section II the actual programs are described in detail and are then placed within the context of the theoretical model. The paper concludes with the policy implications of the analysis.

I. Theoretical Framework

We start with a set of simplifying assumptions which eliminate certain complications from the analysis without severely limiting the generality of the conclusions. First, we measure the impact of housing credit programs by the effect on the flow of mortgage credit and the impact on the terms of credit. While such effects on credit are likely to have an impact on housing activity (since mortgage

Silber wishes to acknowledge the financial support of the Federal Home Loan Bank System. In addition, secretarial assistance was generously provided by the Federal Home Loan Bank of New York. The views expressed are not necessarily shared by the Federal Home Loan Bank System. We wish to thank the following for their comments: Ernest Bloch, Alan Meltzer, Bruce Ricks, and Lawrence Ritter.

flows and rates are related empirically to housing activity),[1] this relationship is not essential for our purposes. Second, the analysis proceeds as though the effectiveness of programs is related solely to their ability to lower the mortgage rate of interest paid by the borrower or increase the flow of mortgage credit. This ignores the fact that most credit programs apply to particular types of mortgages or to particular groups in the population (for example, veterans, poor people, etc.) and that different groups may have different elasticities of demand for housing with respect to the mortgage rate. A detailed comparison of elasticities is beyond the scope of this paper. Third, for simplicity, the mortgage rate of interest is specified as the only determinant of the supply and demand for mortgage funds (implicitly including the amortization period and the loan-value ratio and their impact on mortgage supply and demand). Finally, we also assume that various government programs are well managed and pursue an optimum strategy in trying to achieve their stated goals. For example, we ask what conditions determine whether a well-run secondary market program has a positive impact on the supply of mortgage credit. We do not ask whether the actual secondary market program is well managed.

Given these assumptions, it is useful to classify credit programs as follows:

1) Policies in this category are designed to affect the interest rate paid by mortgage borrowers without changing the risk characteristics of such securities. Two very different techniques are used in the pursuit of this goal: (a) Programs in this subgroup provide *explicit* interest subsidies which introduce a wedge between the mortgage rate received by the lender and that paid by the borrower, usually lowering the latter and raising the former. (b) Policies in this subcategory lower *both* the borrower and lender rates by inducing lending institutions (for example, via portfolio regulations on savings and loan associations) to raise their supply of mortgage funds at all rates of interest. The cost of programs under 1a) are explicit (the subsidy) while cost of programs under 1b) are implicit. The incidence of the costs under 1b) will be discussed below.

2) In this category the programs are designed to first change the risk characteristics of mortgages so that they become more desirable assets to lenders (for example, a reduction in lenders' risk by government insurance and guarantee programs or by the creation of a secondary market). This reduction in risk then raises the supply of mortagage funds and, presumably, lowers both borrower and lender rates. In these programs costs can be both explicit and implicit as we will see below.

This classification of credit programs permits a formal analysis of their relative effectiveness. Policies under 1a) and 1b) will be called wedge-type programs and portfolio-restriction type policies, respectively, and will be discussed first. Programs listed under 2) will be called mortgage characteristic programs, and will be discussed last.

A. *Determinants of Policy Effectiveness*[2]

For any given demand curve for mortgage funds, a wedge-type subsidy on all interest paid attracts more additional funds to the market the more interest elastic is the supply curve of mortgage funds. A highly elastic supply curve exists when mortgages are good substitutes for

[1] For empirical evidence on the impact on mortgage credit and mortgage rates on housing, see Eugene Brady; Ray Fair, ch. 8; Craig Swan.

[2] Work in this area has been done by George Break, Jack Guttentag and D. C. Rao and Ira Kaminow.

other assets in investor portfolios (i.e., a small increase in the relative rate of return on mortgages induces portfolio substitution in favor of mortgages and a corresponding increase in supply).

This positive relationship between the degree of substitutability between mortgages and other securities and the effectiveness of wedge-type subsidies is illustrated in Figures 1(a) and 1(b). The mortgage rate, i_M, is on the vertical axis and the dollar volume of mortgages, $\$M$, is on the horizontal axis. The demand curve for mortgage funds, D, is negatively related to i_M. The supply curve, S, is generally a positive function of i_M. The elasticity of supply is determined by the degree of substitutability between mortgages and other securities. The supply curve shifts with a change in the risk characteristics of mortgages and also shifts when rates on "other securities" change as long as mortgages and other securities are substitutes or complements.

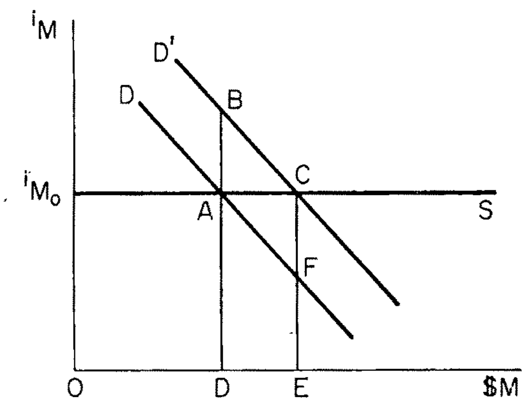

FIGURE 1a

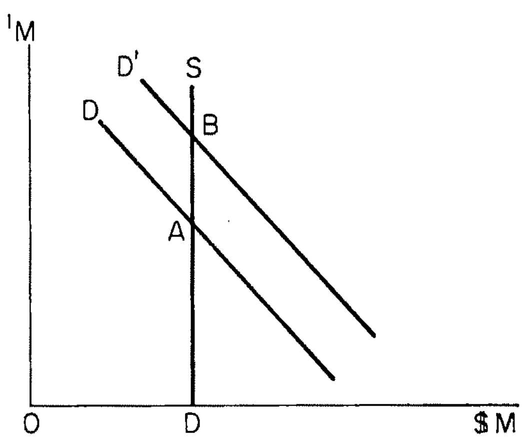

FIGURE 1b

In Figure 1(a), the supply curve of mortgage funds is infinitely elastic at rate i_{M_0}. This situation occurs when mortgages and other securities are perfect substitutes at the existing rate structure.[3] Introducing an interest subsidy to borrowers equal to AB raises the demand curve for mortgage funds to D'. This elicits an increased supply of mortgage funds in the amount DE. The new effective rate to the borrower is EF and the total supply of mortgage funds now stands at OE. Since mortgages and other securities are perfect substitutes, neither i_{M_0} (the rate received by lenders) nor the rate on other securities change, hence, there is no feedback to the supply curve of mortgage funds due to changes in other rates.

In Figure 1(b) the case of an infinitely inelastic supply curve is illustrated, corresponding to the zero substitutability case. Here the effective rate to the borrower remains at DA, the rate received by lenders increases by AB and mortgage funds remain at OD. There is no feedback to the supply curve of mortgages from other securities markets due to the independence condition.

The case of some, but not infinite, substitutability between mortgages and other securities produces results that lie between the extremes in Figures 1(a) and 1(b). In other words, with a positively sloped mortgage supply curve the increase in mortgage funds is less than DE but more

[3] See James Tobin for a discussion of the determinants of substitutability between securities and the definition of perfect substitutes.

than zero and the decline in the effective rate to borrowers is less than CF but more than zero (this result can include a leftward shift in the mortgage supply curve due to a rise in rates on other securities within a general equilibrium framework).

It is also important to note that in this case the source of the subsidy funds has an impact on the general equilibrium solution. If the subsidy funds are raised by floating bonds in the other securities market, this shifts the demand curve for funds in that market upward, raising the rate on other securities, and hence shifting the supply curve for mortgages to the left, thereby partially offsetting the impact of the subsidy. On the other hand, if the subsidy funds come from general tax revenues (or in the extreme from taxes which reduce consumption only), the total supply of funds to the capital market is augmented and there need not be an offset to the subsidy.

The above discussion applies to a uniform subsidy paid on all mortgage interest. There is presently no program of this type; rather, different subsidies are paid to different groups in the population. Some are explicitly aimed at lower income groups and others at middle income groups. The details of such programs will be discussed in Section II.

We now turn to portfolio-restriction type programs. Here we can show that the *lower* the degree of substitutability between mortgages and other securities, the *larger* will be the inflow of funds to the mortgage market (and the larger will be the fall in the mortgage rate) as a result of the restrictions. Note that this substitutability condition is just the reverse of that which made wedge-type programs highly successful.

In Figures 2(a) and 2(b) we have two supply curves of mortgages, S_2, which is the supply curve of the institution (or sector) that is to be subject to restrictions

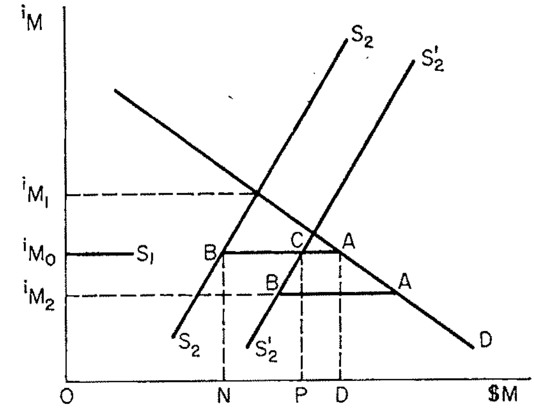

FIGURE 2a

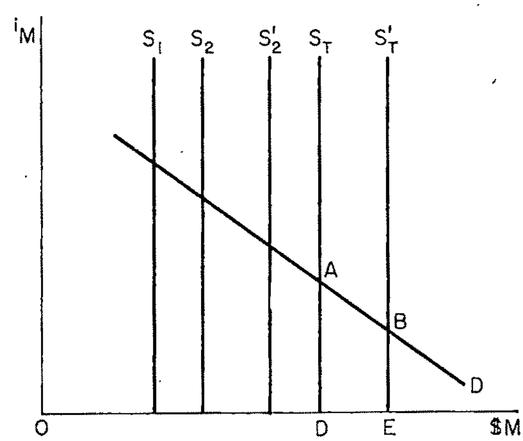

FIGURE 2b

and S_1, which is the supply curve of the unrestricted sector. The sum of the two is the total supply curve of mortgages. In Figure 2(a) the supply curve S_1 is infinitely elastic at rate i_{M_0}, in other words, for the unrestricted sector mortgages and other securities are perfect substitutes at that rate. Without this sector of the market the mortgage rate would be i_{M_1}, (the intersection of S_2 and D). At that rate, however, the unrestricted sector buys mortgages until the market rate is driven down to i_{M_0} at which point total mortgage funds supplied equals OD. The effective total supply curve is S_2BA, with institution 2

buying ON mortgages and the rest of the market buying ND.[4]

The imposition of portfolio restrictions on institution 2, such as via a law which restricts its security holdings to mortgages only, produces a rightward shift in the supply curve of institution 2, say, to S_2'. This rightward shifts occurs as long as the institution initially has a diversified portfolio, i.e., as long as it is a risk averter. If all other participants continue to buy BA (equal to ND) then the mortgage supply curve would be $S_2'BA$ and the mortgage rate would be i_{M_2}. At that rate, however, the unrestricted sector sells mortgages (buying the other securities, institution 2 must sell). Equilibrium is reestablished when the rate is back at i_{M_0} with institution 2 holding OP mortgages and the unrestricted sector holding PD. Total mortgages supplied remains OD. In other words, when restrictions are imposed in a situation where, for the market as a whole, securities are perfect substitutes, there is no impact on the effective mortgage rate or on the supply of mortgage funds.

In Figure 2(b) the extreme opposite case is illustrated. The supply curve of each sector is vertical, implying zero substitutability between mortgages and other securities. The intersection of $S_T(=S_1+S_2)$ and the demand curve, D, produces an equilibrium rate DA. The imposition of restrictions shifts S_2 to S_2', the total supply curve shifts (by the same amount) to S_T' and mortgage funds increase to OE and the rate falls to EB. There is no offset to the increased supply of mortgages by S_2 due to a decreased supply in the unrestricted sector since both supply curves are interest inelastic. There is also no offset due to changes in the rate on other securities because of the independence condition.

[4] Note that the division of mortgage holdings between the two sectors is merely illustrative. The conclusions of this analysis are unaltered by a different distribution.

With some, but not infinite, substitutability between mortgages and other securities the results lie between those depicted in Figures 2(a) and 2(b). In other words mortgage supply rises by less than DE but by more than zero and the rate falls by less than it does in 2(b).

Portfolio restriction policies also impose implicit costs which partially offset their effectiveness, leading, in turn, to further government programs. In particular, forcing an institution to specialize in mortgages (either by explicit regulation or by imposing high reserve ratios against other assets) imposes a higher level of risk per expected rate of return on the institution (compared with unconstrained optimization). In effect the restrictions impose an implicit tax on the institution. As with any other tax, part of the burden (cost) will be shifted away from the institution's owners. For example, if the restricted institution's liabilities are poor substitutes for the liabilities of nonrestricted institutions (and other securities), a reduction in the rate of return on their liabilities does not produce a significant loss of funds. In this case the burden of the restrictions falls mainly on the holders of such liabilities. However, if the nonrestricted sector has securities which are good substitutes, then it will be more difficult for the restricted firms to shift the burden; deposits fall, both of which reduce the scale of their operations. Consequently the restrictions will be less effective in increasing the supply of mortgage funds. In terms of our analysis, the supply curve after restrictions shifts to the left towards its initial position, as other securities are substituted for the liabilities of the restricted institution.

Government guards against this outcome with a variety of complementary programs which either make it easier to shift the burden of restrictions to depositors by restricting the competition for funds, or by compensating the restricted institution with explicit and implicit sub-

sidies. For example, in the past Regulation Q has prevented commercial banks from freely competing with savings and loan institutions for time deposits. In the discussion which follows such policies are referred to as "cost shifting" policies.

Because portfolio restrictions can initially be implemented without cost to the government's budget, they have provided the illusion of being costless to society. In fact, the social cost of effective restrictions may be quite high and it has probably been borne largely by either the owners of the restricted institutions or the owners of particular kinds of deposits depending on the complementary policies adopted by government. With the recent implementation of explicit subsidies (to be discussed in Section II), portfolio restrictions now impose budget costs along with their less obvious other social costs.[5]

There are two ways that portfolio restriction programs may influence the effectiveness of wedge-type programs via an impact on the degree of substitutability between securities. First, going back to the perfect substitutability case depicted in Figure 2(a), if portfolio restrictions are sufficiently pervasive, the rightward shift in the supply curve of the restricted sector could result in the intersection of the demand curve with the supply curve of the restricted sector at a rate below i_{M_0}. The imposition of restrictions then reduces the degree of substitutability between securities for the market as a whole (from perfect substitutability to imperfect substitutability). The second way that portfolio restrictions may change the degree of substitutability between securities for the market as a whole is by changing it in an individual institution's portfolio. (See Silber.) For example, assume the regulation takes the form that the institution must hold at least 50 percent of its assets in mortgages. As the mortgage rate falls relative to other rates the institution can reduce its holdings to a minimum of 50 percent of its assets. After that the elasticity of substitution is zero and the elasticity of supply is zero (for a given level of deposits). Under both circumstances portfolio restrictions reduce the effectiveness of wedge-type programs by reducing substitutability between securities.

We now turn to the impact of mortgage characteristic programs on the supply of mortgage funds. A change in the characteristics of mortgages via, say, government guarantees or the establishment of a secondary market increases lenders' willingness to hold mortgages as investments. With such programs there is an impact on the volume of mortgage funds supplied even with a perfectly elastic mortgage supply curve. This occurs because the reduction in the risk of mortgages relative to the risk of other securities causes a downward shift even in the infinitely elastic supply curve in Figure 2(a).

An important side effect of the programs which lower the riskiness of mortgages is that they also make mortgages better substitutes for other securities. This follows as long as mortgages have greater default risk and a poorer secondary market compared with other securities. Under such conditions government programs make these risk characteristics of mortgages more like those of other securities, thereby increasing the degree of substitutability between mortgages and other securities.[6]

This side effect of mortgage characteristic programs implies that they increase the effectiveness of wedge-type programs and decrease the effectiveness of portfolio restrictions. This is a key interrelationship between existing housing programs as will be seen below. Note also that since the

[5] More extensive commentary on the social and budget costs of these programs appears in Penner and Silber.

[6] See Tobin for a discussion of this relationship between risk characteristics of securities and the degree of substitutability between securities.

mortgage characteristic programs change the slope of the supply curve as well as shifting it, one cannot make any simple statements about the relationship between the efficacy of these programs and the initial degree of substitutability.

II. An Application to Current Credit Programs

This section of the paper applies the theoretical outline set forth above to the current set of federal housing credit programs in the United States that are aimed at the private sector of the economy (i.e., excluding public housing). Existing housing credit programs are categorized according to the classifications outlined in the previous section. Specific analysis of the interaction between the various programs is also presented. It should be noted at the outset that our concern here is not with the income redistribution aspects of certain programs; rather, we are concerned solely with the impact of the program on mortgage credit and mortgage rates.

Table 1 sets forth the main characteristics of the existing housing programs. There are three groups of policies as outlined in the previous section: 1) wedge programs; 2) programs which operate on the risk characteristics of mortgages; and 3) portfolio restriction policies. In the first two columns of Table 1 a brief description of each program is presented as well as a listing of the agency responsible for its execution and the approximate size of the program during the fiscal year 1970.

The programs listed in the first 5 rows of the table are in the wedge-type category. Extensive comments are limited to those programs which have dual listings or may be ambiguous. The programs under sections 235, 236, and 243 (lines 1 and 2) are subsidies rationed out to particular classes of borrowers. Line 3 is the Housing Opportunity Allowance Program (*HOAP*) of the Federal Home Loan Bank System (*FHLBS*) provided under Title I of the Emergency Home Finance Act of 1970. A direct subsidy to mortgage borrowers is offered. Line 4 of Table 1 is the Tandem plan, implemented by the Government National Mortgage Association (*GNMA*) in "tandem" with the Federal National Mortgage Association (*FNMA*). The Tandem plan operates to produce a wedge when the FHA-ceiling rate is below market rates. Tax benefits (in particular, deductibility of mortgage interest in calculating taxable income) in line 5 also inserts a wedge between borrowers and most lenders. This wedge is operative as long as the income tax rate applicable to borrowers exceeds the tax rate paid by lenders (which is the likely case due to the favorable tax treatment of the major mortgage lenders, *S&L*'s, and mutual savings banks).

The next four lines of Table 1 list the housing credit programs aimed at altering the risk characteristics of mortgages. Line 6 records the secondary mortgage market operated by *FNMA* and Federal Home Loan Mortgage Corporation (*FHLMC*). The existence of these two institutions implies that mortgages are more liquid than otherwise because *FNMA* and *FHLMC* stand ready to make a market in existing mortgages.

This secondary market function of *FNMA* and *FHLMC* should be distinguished from the countercyclical and secular purchases of mortgages by these institutions which appear in line 11 of the table under portfolio restriction programs. *FNMA* in particular has behaved more like a financial institution restricted to mortgage holdings. Since both *FNMA* and the *FHLMC* have a government-imposed directive to support housing, they buy mortgages when there is a significant

TABLE 1—PROGRAM CHARACTERISTICS

Program	Agency and Program Size	Short Description	Source of Funds	Benefits as related to Substitutability Between: Mortgages and Other Primary Securities	Benefits as related to Substitutability Between: Deposits and Other Primary Securities
Wedge-Type					
1. Sec. 235 & 236	HUD In 1970, housing starts under these programs totalled 116 thousand units. The budget request for these two programs totalled $245 million. (Note all years refer to fiscal year.)	Subsidizes FHA-VA mortgage interest rate (to as low as 1 percent for low income single family (235) and multi-family (236) housing. Authority granted in Housing and Urban Development Act of 1968. (Programs were suspended Jan. 1973.)	U.S. Treasury	+	+
2. Sec. 243	HUD This program has never been funded. While not yet operational the administration has considered implementing the program.	Subsidizes FHA-VA or conventional mortgage interest rate (to as low as 7 percent) for middle income borrowers. Authority granted in Emergency Home Finance Act of 1970.	U.S. Treasury	+	+
3. Title I, *HOAP* (Housing Opportunity Allowance Program)	*FHLB* In 1971, $51 million was obligated. (Program no longer operative.)	*FHLB* subsidizes mortgage rate *S&Ls* charge their borrowers. As currently operated by the *FHLB*, a borrower's monthly payments are reduced by as much as $20 for a period of 5 years.	U.S. Treasury	+	+
4. Tandem	HUD, *GNMA*, *FNMA* The program was expanded in 1972. There is an authorization for $2.0 billion under the program.	When the effective rate on FHA-VA mortgages is above the ceiling rate, *GNMA* buys mortgages at par and resells them at a discount to *FNMA*. This insures the borrower of not paying the discount points in the form of, say, higher prices for a given house. Developed under HUD Act of 1968.	U.S. Treasury	+	+
5. Tax Benefits	U.S. Treasury, Congress	Homeowners may deduct mortgage interest payments in calculating taxable income for the personal income tax.	U.S. Treasury	+	+
Mortgage Characteristics					
6. *FNMA/FHLMC* Secondary Mortgage Market	*FNMA*, *FHLMC*	*FNMA* and *FHLMC* stand ready to buy and sell existing mortgages at market prices. *FNMA* was established in 1934 under the National Housing Act of 1934. The status of *FNMA* was altered in the Housing Act of 1954 and the HUD Act of 1968. The *FHLMC* was created by the Emergency Home Finance Act of 1970.	Borrowing from the public via agency issues plus back-up borrowing capability at the Treasury.	0	0

Program	Agency and Program Size	Short Description	Source of Funds	Benefits as Related to Substitutability Between: Mortgages and Other Primary Securities	Benefits as Related to Substitutability Between: Deposits and Other Primary Securities
7. VA subsidized guarantees	Veterans Administration. During 1970 there was a net increase of $1.1 billion in guranteed mortgages.	Mortgages are guaranteed by the Veterans Administration for qualified veterans of the United States.	U.S. Treasury	0	0
8. FHA Unsubsidized insurance	HUD, FHA During 1970 there was a net increase of $4.6 billion in insured mortgages.	Mortgages can be insured by HUD under sections 203 and 207 of the National Housing Act of 1949. Premiums are paid by borrowers for the insurance.	Insurance premiums from borrowers. Back-up funds from Treasury equalled $339 million in 1970. Reserves from premiums paid totalled $1,203 million in 1970.	0	0
9. *GNMA* Guarantees of mortgage backed bonds.	*GNMA* During 1970 GNMA guaranteed $441 million of securities.	*GNMA* guarantees securities which are issued by private investors when their securities are backed by FHA-VA mortgages. Authorized under the HUD Act of 1968.	U.S. Treasury	0	0
Portfolio Restrictions					
a. Direct Measures					
10. *S&L* portfolio restrictions	*FHLB*	Savings and Loan Associations are permitted to hold only government bonds, mortgages and the issues of U.S. government agencies.		—	—
11. *FNMA* and *FHLMC* purchases	*FNMA* *FHLMC* During 1970 the net change in outstanding loans totalled $5.4 billion for *FNMA*. The *FHLMC* was not operational until mid-1971.	*FNMA* and *FHLMC* buy and sell mortgages in order to moderate cyclical swings in mortgage rates and credit.	Borrowing from the public via agency securities plus back-up borrowing capability at the Treasury (back-up funds equal $2.25 billion).	—	—
b. Cost-shifting Measures					
12. Deposit Insurance	*FHLB* via Federal Savings and Loan Insurance Corporation.	Deposits at *S&L*s are insured.	Premiums paid by *S&L*s plus back-up funds from Treasury. In 1970 paid-in reserves totalled $2.4 billion while the back-up authority was $750 million.	0	—

TABLE 1—(*Continued*)

Program	Agency and Program Size	Short Description	Source of Funds	Benefits as Related to Substitutability Between: Mortgages and Other Primary Securities	Benefits as Related to Substitutability Between: Deposits and Other Primary Securities
13. Regulation Q	Federal Reserve Board	Commercial bank time deposit rates are regulated by the Federal Reserve. Until 1966 such limitations curbed the competitive position of banks for savings. Since 1966 *S&Ls* have also had regulations on their deposit rates.	Not applicable.	0	—
14. *FHLB* unsubsidized lending	*FHLB* During 1970 the net change in outstanding loans totalled \$3.8 billion.	*S&Ls* are permitted to borrow at the *FHLB*. The rate charged depends upon the rate paid by the *FHLB* for funds.	Borrowing from the public via agency issues plus back-up borrowing capability equal to \$4.0 billion at the Treasury.	—	—
15. *FHLB* subsidized lending	*FHLB* Not implemented as yet.	The *FHLB* lends to *S&Ls* at subsidized rates. Authorized by Title I of the Emergency Home Finance Act of 1970.	U.S. Treasury	—	—
16. Favorable tax treatment of *S&Ls*	U.S. Treasury, Congress		U.S. Treasury	—	—

contraction in the volume of credit supplied by private institutions. Conceptually, if not empirically, these are quite distinct. Note that both *FNMA* and the *FHLMC* are subsidized by the government because each has a line of credit at the Treasury. In other words, the costs of the restrictions on *FNMA* and the *FHLMC* are shifted to the tax paying public because of the potential cost of the line of credit at the Treasury.

Line 7 lists the Veterans Administration mortgage guarantee program which insures holders of VA mortgages against default. The elimination of default risk increases the supply of such mortgage funds, lowering the contract mortgage rate and easing terms of credit. Since the borrowers do not pay the insurance premium the effective rate to the borrower is in fact lowered.

Line 8 lists the FHA-unsubsidized insurance program. Under this program the mortgage borrower pays an insurance premium to the government. While the contract mortgage rate is reduced (and terms of credit eased) after the guarantee is in existence, the effective rate (i.e., the

contract rate plus the insurance premium) to the borrower might very well be unchanged if the insurance premium were equal to what the private sector would charge (equal to expected loss plus administrative costs). There is one aspect of the program, however, which does produce a subsidy in the form of lower insurance premiums than otherwise, namely, the back-up funds authorized by Congress to be used in case defaults exhaust paid-in funds.

Line 9 lists another type of guarantee program by *GNMA*. Mortgage lenders who hold FHA-VA mortgages can now issue bonds insured by *GNMA* to finance these acquisitions. It is included under programs operating on mortgage characteristics because it has the same effect as increasing the "pledgeability" of mortgages as security.

There is an element of cost shifting in all of these programs operating on mortgage characteristics. By reducing the risks on mortgages they also counteract the burdens imposed by forcing an institution to hold mortgages. However, these programs are aimed primarily at voluntarily increasing the supply of mortgage funds from both restricted and unrestricted investors by lowering the risks on mortgages. The fact that they ease the burden imposed by restrictions just happens to be a desirable side effect.

The next group of programs comes under the heading of portfolio restriction policies. These policies are divided into two groups: (a) direct measures and (b) cost shifting measures. Lines 10 and 11 include the direct measures, i.e., portfolio restrictions on *S&L*'s (limiting them to holding mortgages, governments and agency issues) and the countercyclical and secular mortgage purchases of *FNMA* and the *FHLMC*.

The first two cost shifting programs are deposit insurance in line 12 and Regulation Q in line 13. Both of these measures try to offset the potentially adverse impact on deposits of the poorer risk/return tradeoff in *S&L* portfolios due to mortgage specialization. Note that in the case of deposit insurance, although premiums are paid there are back-up budget funds which presumably make premiums less than what would be charged privately. The subsidy in this case is similar to FHA-unsubsidized insurance.

Lines 14 and 15 include Federal Home Loan Bank (*FHLB*) subsidized and unsubsidized lending to *S&L*'s as cost shifting measures. The unsubsidized lending by *FHLB* contains some subsidy, hence, cost shifting, because the rate the *FHLB* pays on its liabilities is less than that of a private corporation because there is back-up authority for borrowing at the Treasury.

Line 16 lists the favorable tax treatment received by *S&L*'s as a cost shifting measure. While the tax treatment of *S&L*'s was made more stringent in the Tax Reform Act of 1969 they still retain significant tax benefits compared with unrestricted financial institutions.

A. *Interrelationships between and Impacts of Programs*

The first column of Table 1 lists the agency charged with administering the program and also provides a rough estimate of the size of the program during the fiscal year 1970. It is important to recognize that these numbers are not comparable between different programs. In some cases, such as 235 and 236, the subsidy as measured by actual budget costs is listed, while for others, such as *FNMA-FHLMC* operations, the total purchases of mortgages is listed. The implicit subsidy in the latter case is simply not known.

The ultimate measure of a program's effectiveness is its impact on mortgage

credit and housing production. While the table includes (where available) the number of houses constructed or the number of mortgage loans made under various programs, it is incorrect to use such numbers as measures of a program's impact. Clearly they do not record the *increment* in housing or credit due to the subsidy.

We noted in the beginning of Section I that increased mortgage credit tends to increase actual housing production. This is not necessarily the case. In fact the size of the impact may depend upon the nature of the particular credit program. For example, the funding of programs 235 and 236 does not permit the granting of subsidies to all who qualify legally. The funds must be rationed by administrative action. A key to the size of the impact of such credit on housing production is, therefore, the skill of the administrators in isolating potential homebuyers who are at the margin, i.e., who would withdraw from the market without the subsidy.

The specific nature of the subsidy calculation poses a related problem. The homeownership assistance subsidy under 235, for example, is set to either lower the mortgage interest rate to one percent or to lower the payment for the sum of mortgage interest, taxes and insurance to 20 percent of the owners income, whichever is less. If the size of the subsidy depends on the recipient's income (the second option) and he expects that his future income will not rise sufficiently to end the subsidy, then he has a strong incentive to maximize the size of the mortgage and to purchase the highest quality home since such quality improvements impose no personal marginal costs (they are borne entirely by the subsidy). This feature of the 235 program, i.e., relating the subsidy to the recipients' income, has probably raised the expenditures per housing unit. With a given budget for the 235 program, this might also imply a reduction of the quantity of new units constructed.[7]

In column 3 of Table 1 the source of funds for each program is listed. In some cases there is a primary source and a secondary or back-up source. As we noted earlier, the use of borrowing from the private capital market produces less of an impact than the use of general tax revenues. Similarly, the use of fees and charges produces a smaller impact than using general tax revenues. Obviously, however, direct costs are smaller in the borrowing and user-charges cases compared with tax revenues.

Columns 4 and 5 lists the relationship between types of substitutability and the benefits of each program. Benefits are defined as increased mortgage credit (or lower mortgage rates to borrowers). The question asked was as follows: for a given dollar level of activity of the program would mortgage credit increase (+), decrease (−), or remain the same (0) if there was an increase in the degree of substitutability between X and Y (where X and Y were either mortgages, other primary securities, or deposits of mortgage lending institutes). Note that the heading of the column could have been listed as "costs as related . . . " and the question asked could have been: for a given volume of mortgage credit (or rate charged to borrowers) would the dollar cost of the program increase, decrease, etc. . . . In other words, benefits and costs as defined here are related symmetrically to the substitutability question.

In Table 2 the interrelationships between the various programs are outlined. A posi-

[7] The redistribution goals of 235 and 236 programs may be better served by income-related subsidies. Yet even this is not clear. In the fourth quarter of 1971 the median annual income of families receiving 235 subsidies was $6,309, with only 3.9 percent of the families having an income below $4,000 (see p. 29 in *The Fourth Annual Report on National Housing Goals*).

tive relationship (+) between two programs occurs when the initiation, or increased level of activity, of program X causes an increase in the benefits or a reduction in the costs (as defined above) derived from a given level of program Y. Zero and negative relationships are defined in the same way with the appropriate changes.

Columns 1 through 5 indicate that wedge-type programs have no effect on the efficacy of any of the other housing programs. The impacts of the mortgage characteristic programs (6, 7, 8, and 9) are based on the assumption that, in general, mortgages have greater default risk and marketability risk compared with other securities (for example, corporates and governments) and that these risk differences imply a lower degree of substitutability between mortgages and other securities than would otherwise exist. Any program which reduces the default and marketability risks of mortgages (making these risks more like those on other securities) also makes mortgages better substitutes for other securities. The positive relationship between mortgage-characteristic programs and the wedge-type programs (1–5) and the negative relationship between mortgage characteristic programs and portfolio restrictions (10–11) follows directly. Since the five cost-shifting programs (12–16) seek to offset the costs of restrictions, the effectiveness of any given cost-shifting measure is increased the lower is the "cost" of the restrictions, i.e. the greater the similarities between mortgages and other securities. Hence, there is a positive relationship between the mortgage characteristic programs and the cost-shifting measures.

The relationship between the mortgage characteristic programs and the other programs would be reversed if the marketability and default risks of mortgages were lower than those on other securities. This situation cannot occur as long as there is a security such as government bonds which have zero default risk and the "most efficient" secondary market possible given the existing financial technology.

The impact of any one of the mortgage characteristic programs on any of the others is probably zero unless one wishes to argue that there are "diminishing returns" to guarantees on top of guarantees. Under such circumstances, the existence of FHA and VA guarantees is negatively related to the effectiveness of *GNMA* guarantees of mortgage-backed securities.

The last group of programs, portfolio restriction policies, is a self-contained group as far as interrelationships are concerned. Neither *S&L* portfolio restrictions nor countercyclical mortgage purchases by *FNMA* and the *FHLMC* have any impact on the efficacy of other programs.[8] In a very limited sense the existence of restrictions on *S&L*'s makes the cost-shifting measures relevant; however, an increased level of restrictions does not make a given level of cost shifting more effective.

The impacts of the cost-shifting measures on *S&L* restrictions is clearly positive since, if these cost-shifting programs did not exist, the risk/return position of the restricted industry would be worsened and the captive demand for mortgages would be reduced (as firms left the industry and as depositors substituted other securities for deposits). The only cost-shifting measure which increases the efficacy of *FNMA* and *FHLMC* mortgage purchases is Regulation Q (since it reduces the competition for *FNMA-FHLMC* obligations from commercial bank time deposit liabilities).

[8] We noted above that portfolio restrictions on *S&L*'s might reduce the degree of substitutability between mortgages and other securities. Since there is uncertainty with regard to this effect we chose not to include in the table a negative impact of portfolio restriction policies on the wedge-type programs.

III. Conclusions

The key determinant of the effectiveness of two of the three housing finance programs is the degree of substitutability between mortgages and other categories of securities. Wedge-type programs are most effective with high substitutability while portfolio restrictions are most effective with poor substitutability. In a world of perfect certainty the degree of substitutability would be known, hence the precise benefits (in terms of mortgage credit diverted or reduction in rates) could be calculated for each program. These benefits could be compared with the associated costs and an unambiguous optimal policy to divert funds to the mortgage market would emerge.

Policy decisions, however, must be made under conditions of uncertainty with regard to the parameters which determine the effectiveness of each policy. Under such circumstances it has been shown that diversification of policy tools is the optimum strategy. (See William Brainard.) Hence, the simultaneous use of wedge-type programs and portfolio restriction policies is a desirable strategy.

The fact that the effectiveness of mortgage characteristic programs is independent of substitutability between mortgages and other securities suggests that they too should be included in the diversified policy strategy. It does not imply that exclusive reliance be placed on such policies since the cost per increased output of houses may be much larger than for either of the other programs.

The fact that mortgage characteristic programs increase the degree of substitutability between mortgages and other securities has one clear implication: wedge-

type programs become more effective while portfolio-restriction policies become less effective. This might help justify or explain the relatively late emergence of wedge-type programs compared with portfolio restrictions. As mortgage guarantees and the establishment of a secondary market made mortgages better substitutes for other securities, the effectiveness of portfolio restrictions declined and the effectiveness of wedge-type programs increased. However, not only do portfolio restrictions become less effective ways of increasing mortgage funds, they also become less harmful to the restricted institution. The reduction in the burden of restrictions caused by the expansion of the programs which reduce risk (as well as the provision of subsidized loans to $S\&L$'s) has probably been important in allowing government to suspend part of Regulation Q and to recommend its permanent elimination.

On Monopoly Welfare Losses

By ABRAM BERGSON*

Are welfare losses due to monopolistic pricing apt to be consequential in an advanced economy such as that of the United States? Generations of economists have assumed that they are, but in 1954 Arnold Harberger argued that in the United States during the late 1920's, the total of such losses in manufacturing was equivalent to but "... a tenth of a percent of national income" (p. 87). Subsequently, David Schwartzman found that in the United States in 1954 welfare losses due to monopolistic pricing in industry were equivalent to "... less than $234 million, or less than 0.1 percent of the national income" (pp. 629–30). Still more recently Harvey Leibenstein, relying partly on the findings of Harberger and Schwartzman, has also argued that departures from competitive norms such as result under monopolistic pricing are likely to be relatively inconsequential. Generally, "... they hardly seem worth worrying about" (Leibenstein, p. 395).

From such findings, George Stigler was an early dissenter and further calculations of David Kamerschen indicated that welfare losses due to monopoly pricing may be appreciably greater than Harberger and Schwartzman computed. The contention that such losses are inconsequential nevertheless has apparently gained no little currency. Perhaps that is as it should be, but the underlying methodology still does not seem to have been sufficiently explored. Some of the more basic empirical assumptions may also be more questionable than has been supposed. A brief reexamination stressing those aspects may facilitate appraisal of what is surely one of the more important current issues in economics.

I. Some Methodological Considerations

The evaluations of monopoly welfare losses by Harberger, Schwartzman, and Leibenstein all represent applications of consumer's surplus analysis. As such, they are in a sense rather special, for expressly or by implication, all these writers apply a well-known formula of Harold Hotelling for such surplus. Their calculations may also be viewed, however, as measurements of consumer's surplus without reference to the Hotelling formula. As a preliminary, I briefly reformulate the relevant principles, which still seem somewhat in need of clarification.

What counts for Harberger, Schwartzman, and Leibenstein is efficiency rather than equity. I assume, therefore, as is often done in similar contexts, that there is but one household in the community. The household, however, behaves competitively in purchasing consumer's goods. As will appear, the analyses being considered also assume constant costs. For present purposes it is more convenient to work with the somewhat more restrictive supposition that the community's production possibilities are linear.

As J. R. Hicks taught us long ago, consumer's surplus is susceptible to diverse constructions. The particular construction need not be a practically very important matter, but we may conveniently consider the evaluations that have been made in relation to a concept of surplus corresponding to the compensating variation as understood by Hicks (see pp. 61ff, 69ff),

* Harvard University.

i.e., the compensatory change in income needed to assure that a household's utility is unaffected by a change in price.

For Hicks, however, the compensating variation represents a change from an otherwise given income. Such a variation is properly taken to measure welfare losses or gains if income is indeed constant. Our household, however, is subject not only to changes in prices, those being the changes due to the fixing of the prices in monopolistic industries at monopolistic rather than competitive levels, but also to a concomitant variation in income. In the analysis of monopoly welfare losses, the concern is with the impact of misallocation rather than unemployment. Hence, with the prices of monopolistic products at monpolistic rather than competitive levels, resources released from monopolistic industries supposedly are reemployed in competitive ones. That is possible only if household income is higher when prices in the monopolistic industries are at monopolistic levels than when they are at competitive levels. Indeed, income must increase by the amount of monopoly profits, for only in that way will there still be sufficient income to employ all the primary factors previously employed.

In short, we are confronted with variations within a general equilibrium context. In consumer's surplus analysis the usual practice even so is to focus on partial equilibrium, but the analysis here seems facilitated if general equilibrium is put clearly to the fore, and Hicks' compensating variation is viewed accordingly.

Thus, a distinction is made between the *gross* compensating variation (GCV), representing the change in income needed to compensate households for some specified variation in prices, and the *net* compensating variation (NCV), representing the gross change, less the adjustment in income (MIA) required to maintain full employment in the face of such a variation in prices, i.e.,

$$NCV = GCV - MIA \tag{1}$$

The GCV corresponds to what Hicks called compensating variation, but the NCV is of primary interest here.[1]

Of particular concern now is a rise in prices in monopolistic industries to monopolistic from competitive levels. Referring to such price changes, it suffices here if there is but a single competitive industry in the community considered. If for the moment we also assume that there is only one monopolistic industry, the price and income variations of interest may be illustrated graphically. In Figure 1, x_1 is the product of the monopolistic and x_2 the

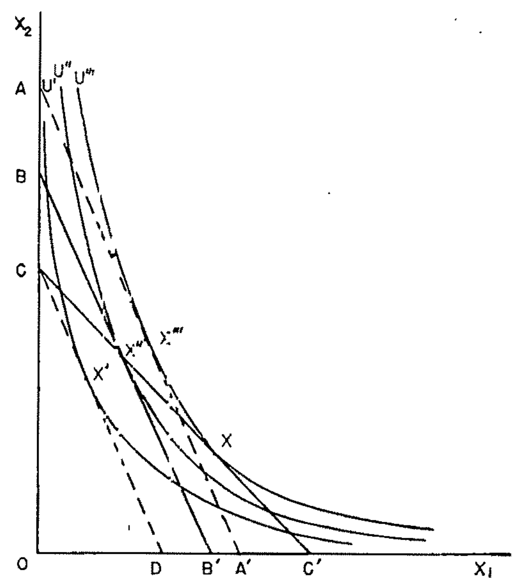

FIGURE 1

[1] For simplicity I assume throughout that monopoly price-cost ratios are unchanged under the impact of the changes in household income in question, but it is easy to see that no essentials would be affected if the ratios should vary. What counts are the monopolistic price-cost ratios when income is again at the full employment level, and the GCV could simply be understood as the addition to the household's initial income level that is needed to compensate for the charging of those price-cost ratios. The MIA is calculated as before as the difference between the two full employment income levels, one where monopolistic products are priced monopolistically and the other where they are priced competitively.

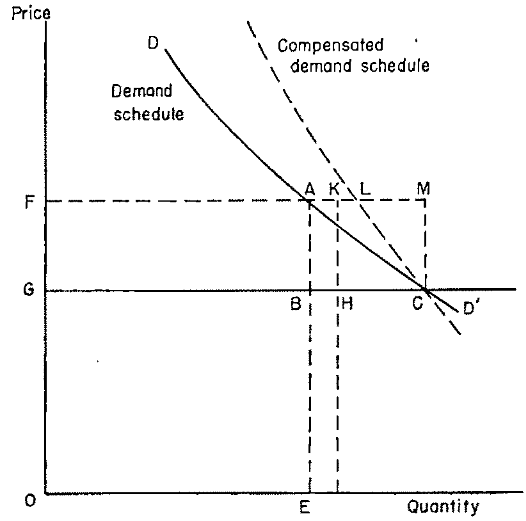
product of the competitive industry, and CC' represents, the community's production possibilities. Several of the household's indifference curves are also shown, and the point x on U''' represents the household's consumption as it would be if there were competitive pricing throughout the economy, i.e., price equals marginal costs in both the monopolistic and the competitive industries. At x' on U' the household's consumption is as it would be if under monopolistic pricing for x_1 the household's income (with x_2 as the numeraire) should be constant at the competitive level OC. With consumption at x', however, there would be unemployed resources, and that is avoided only if income rises by BC to OB, permitting consumption under monopolistic pricing for x_1 to be at x''. That point is again on the production possibilities schedule, and also on U''. The household has still suffered a welfare loss, though, as a result of monopolistic pricing for x_1. The loss is represented by the shift from U''' to U'', but this would be fully offset were there a further increase in income by AB, that would permit consumption to rise to x''' on U'''. Such consumption, of course, is not feasible, but the increase in income by AB still can serve as a hypothetical measure of the welfare loss due to monopoly.

Thus, AB represents the NCV for monopolistic pricing as that has been defined. We also have

$$AB = AC - BC \tag{2}$$

where AC corresponds to the GCV for monopolistic pricing, and BC represents the MIA, or increase in income above the competitive level that is needed to maintain full employment under monopolistic pricing for x_1.

I have delineated the NCV in terms of the household's indifference map. Could it be calculated from a conventional Marshallian demand schedule for the monopolized product? Subject to one proviso, it could be, for the NCV then precisely corresponds to the triangle-like area ABC in Figure 2. Here DD' represents the Marshallian demand schedule for x_1 that prevails when household income is at a level that would assure full employment under competitive pricing for x_1. Since costs are constant, such pricing means that x_1 would sell at average cost, equalling OG. Under monopoly, however, the price is increased to OF.



OF = Monopoly Price
OG = Competitive Price
FK = Monopoly Output After Adjustment in Money Income to Assure Full Employment

Figure 2

The proviso is the proverbial one that the income elasticity of demand for the product in question be zero. In that case, the budget points x', x'', and x''' in Figure 1 all include the same x_1 and differ only in respect of x_2. Also, the GCV, or AC in that figure, corresponds to the area ABC together with the rectangle $FABG$ in Figure, 2, for "income effects" that might distort the relation between the sum of those areas and the GCV are zero (see Hicks, pp. 68ff). It also follows that the MIA, or BC in Figure 1, corresponds to the rec-

tangle *FABG* in Figure 2. Given that the consumption of x_1 in x' is the same as in x'', the x_1 in x'' corresponds to *FA*. Hence, *FABG* represents monopoly profits at a full employment income level, and also the addition that must be made to income if the resources released from x_1 by the introduction of monopolistic pricing there are to be fully absorbed into x_2. It also follows that the *NCV*, or *AB* in Figure 1, corresponds to the area *ABC* in Figure 2, which is in effect the difference between the *GCV* and *MIA*.

What if the income elasticity of demand is other than zero? As is well known, calculation of the Hicksian compensating variation from a Marshallian demand schedule in that case is subject to error. That must be so also, therefore, for the *GCV*, but of interest here is the *NCV* so we must also consider that the *MIA*, as just calculated, is likewise subject to error. Curiously, the errors tend to be offsetting.

Thus, suppose the monopolized product is a superior one. Then the *GCV* for an increase in the price of that product from the competitive to the monopolistic level now corresponds to the area that is bounded by that price change to the left of the Hicksian or compensated demand schedule, that is, the area *FLCG* in Figure 2. That area exceeds the corresponding area, *FACG*, to the left of the Marshallian or uncompensated demand schedule, which previously represented the *GCV*. On the other hand, monopoly profits at a full employment income level and hence the *MIA* also increase, and are now represented by the area *FKHG* in the figure, rather than the area formerly considered, *FABG*. That follows at once from the fact that *FK* corresponds to x_1 in x'', and is thus intermediate between x_1 in x', or *FA*, and x_1 in x''', or *FL*.

Since the monopolized product must be supposed to be absorbing a large part of the household's income, the first of these income effects should often be rather large. Presumably that would ordinarily be true also of the second. But as indicated the two effects should also be mutually offsetting. How the *NCV*, now given by the area *KLCH* (i.e., the excess of *FLCG* over *FKHG*), compares with the area *ABC*, is nevertheless not an easy subject for generalization. For a superior good, however, it might be supposed that, as given by the *NCV*, the welfare loss would, if anything, be understated by an area such as *ABC* in Figure 2. Curiously that need not be so, for the error in the *GCV* might be more than offset by the further one in the *MIA*. For diverse linear demand schedules it can be shown that that is in fact the case.[2]

Proceeding more formally, we may readily extend the analysis to many monopolized products. Suppose there are n goods that are monopolized, and that a single product, $(n+1)$, is competitive. If we take that as numeraire, there are n prices, $p_1 \ldots p_n$, which vary from $p_1^c \ldots p_n^c$ to $p_1^m \ldots p_n^m$. Household income is I, and in the initial equilibrium,

[2] Reference is to demand schedules for the monopolized product of the form:

$$x = ap + bI + c$$

where x is the consumption of the monopolized product (for convenience, I omit subscripts at this point), p is its price, I is income, and a, b, and c are constants. This formula represents a family of Marshallian or uncompensated demand schedules, each such schedule corresponding to a given level of I. From the Slutsky equation, I derive a formula for the corresponding Hicksian or compensated demand schedules, and on this basis calculate the value of *NCV* corresponding to the area *ABC* and that corresponding to the area *KLCH* in Figure 2 under alternative assumptions as to the uncompensated price elasticity (η_{xp}) and income elasticity (η_{xI}) of demand in the vicinity of the full employment equilibrium with monopolistic pricing for x. With $\eta_{xp}=1.5$ and $\eta_{xI}=1.0$, I find that the *NCV* corresponding to *ABC* is 1.04 and that corresponding to *KLCH*, .77 percent of household income. The corresponding measures of *NCV* when $\eta_{xp}=6.0$ and $\eta_{xI}=3$ are 4.17 and 3.88 percent of household income. I assume that x accounts for one-half the household budget under full employment equilibrium with monopolistic pricing for x, and that with that pricing p is 20 percent above costs.

I^c. Then the household's utility may be written as a function:

$$(3) \qquad U = U(p_1, \ldots, p_n, I)$$

Hence, the GCV is such that

$$(4) \quad U(\overset{c}{p}_1 \ldots \overset{c}{p}_n, I^c) = U(\overset{m}{p}_1 \ldots \overset{m}{p}_n, I^c + GCV)$$

According to a well-known formula due mainly to Hicks (pp. 169ff), we also have

$$(5) \qquad GCV = \sum_{i=1}^{n} gcv_i$$

In (5), GCV is as before, though now changes in many prices together are being compensated for. Also, gcv_i is the gross compensating variation for the increase in the price of the ith of n monopolized products. The gcv_i for those products, however, must be determined sequentially. Thus, if they are treated in the order in which the products are numbered, then for gcv_j reference is to the income increment that would be needed to compensate for the increase in the price of the jth product when prices for all products $l \ldots (j-1)$ have already changed and have been compensated for.[3]

[3] So far as it is understood that in the determination of gcv_j, previous price changes have been compensated for, this formulation seems somewhat novel. That gvc_j must be so construed, however, is seen at once when we consider that with that construction:

$$U(\overset{c}{p}_1, \ldots, \overset{c}{p}_j, \ldots, \overset{c}{p}_n, I^c) = U(\overset{m}{p}_1, \overset{c}{p}_2, \ldots, \overset{c}{p}_j, \ldots, \overset{c}{p}_n, I^c + gcv_1) = \ldots$$

$$U\left(\overset{m}{p}_1, \ldots, \overset{m}{p}_{j-1}, \overset{c}{p}_j, \ldots, \overset{c}{p}_n, I^c + \sum_{i=1}^{j-1} gcv_i\right) = \ldots$$

$$= U\left(\overset{m}{p}_1, \ldots, \overset{m}{p}_n, I^c + \sum_{i=1}^{n} gcv_i\right)$$

Then,

$$U(\overset{m}{p}_1, \ldots, \overset{m}{p}_n, I^c + GCV) = U\left(\overset{m}{p}_1, \ldots, \overset{m}{p}_n, I^c + \sum_{i=1}^{n} gcv_i\right)$$

Since utility is supposed to vary monotonically with I, (5) follows.

It also follows that GCV may still be evaluated from uncompensated demand schedules, but for each gcv_i constituting it reference, strictly speaking, must be to that uncompensated schedule for x_i conforming to the indicated determination of gcv_i. Thus, suppose the demand function for the jth product is given by

$$(6) \qquad x_j = d^j(p_1 \ldots p_j \ldots p_n, I)$$

Then gcv_j is to be calculated from the particular member of that family given by

$$(7) \quad x_j = d^j\left(\overset{m}{p}_1 \ldots \overset{m}{p}_{j-1}, p_j, \overset{c}{p}_{j+1} \ldots \overset{c}{p}_n, I^c + \sum_{i=1}^{j-1} gcv_i\right)$$

Each and every gcv_i as so calculated is precisely correct and all together sum to GCV if income elasticities of demand for all monopolized products are zero, but otherwise calculated gcv_i and the resulting GCV will err in one way or another. Of course, if income elasticities were zero, there would also be no need to be concerned about the precise level at which money income is held constant in each demand schedule, for example, whether at I^c or at I^c plus a sum such as appears in (7).

In order to obtain the NCV, we must deduct from GCV the MIA, the adjustment in income needed to assure full employment in the face of all price changes together. Here

$$(8) \quad MIA = \sum_{j=1}^{n} mia_j = \sum_{j=1}^{n} (\overset{m}{p}_j - \overset{c}{p}_j)\overset{m}{x}_j$$

where $\overset{m}{x}_j$ is the consumption of x_j, when all prices of monopolized goods are at monopoly levels and income has been increased to $(I^c + MIA)$, i.e.,

$$(9) \quad \overset{m}{x}_j = d^j(\overset{m}{p}_1 \ldots \overset{m}{p}_j \ldots \overset{m}{p}_n, I^c + MIA)$$

MIA is determined in principle, along with x_j^m, from (8) together with (9) for $x_j^m, j=1 \ldots n$.

Might we also calculate *NCV* as so determined simply by summing areas such as *ABC* in Figure 2? To calculate such areas, reference here presumbaly should be made to demand schedules corresponding to that for x_j in (7) when all prices other than p_j are at competitive levels while I corresponds to I^c, or full employment income when prices are at competitive levels. On that understanding, the answer to the question posed is in the affirmative under two conditions: (i) The income elasticity of demand for every monopolized good is zero. (ii) Cross elasticities of demand among all monopolized products are zero.

Actually, under these conditions it is immaterial at what levels prices of products other than the one considered and income are held constant in the calculation of an area such as *ABC*, for then all terms other than the price of the product in question drop out of the formulas for the demand for x_j in (7) and (9). The uncompensated demand schedule for any good also coincides with its compensated demand schedule. Hence for any x_i, the areas *FACG* and *FABG* in Figure 2 precisely correspond to gvc_j and mia_j. The difference between the aggregate of areas such as *FACG* and the aggregate of rectangles such as *FABG*, and hence also the resulting aggregate of areas such as *ABC*, for all commodities, also precisely correspond to the *NCV*.

What if the stated conditions are not met? In that case, the aggregate of areas such as *FACG* can only be expected to diverge from the *GCV*, since for any x_j such an area will differ from the gcv_j. That will be so insofar as: (i) The gcv_j is properly calculated from a demand schedule such as that in (7), where prices for products other than x_j are held constant, some at monopolistic and some at competitive levels, and income is held constant at a level corresponding to that indicated in (7); and (ii) There are income effects of the usual sort, i.e., those manifest in a divergence between the compensated and uncompensated demand schedules for x_j. Similarly, the sum of areas such as *FABG* can hardly be expected to correspond with the *MIA* as given by (8) and (9). As in the case of a single monopolized product, errors at different points may sometimes tend to be offsetting. So far as products generally are more often substitutes than complements, that, as easily seen, is apt to be so regarding errors due, on the one hand, to the difference between uncompensated and compensated demand schedules and, on the other, to the difference between the sum of rectangles such as *FABG* and the *MIA* as given by (8) and (9). Nevertheless, the relation of the sum of areas such as *ABC* in Figure 2 to welfare losses as given by the *NCV* is rather complex. Without a detailed knowledge of demand functions, in all their dimensions, i.e., demand functions such as (7), we cannot really tell how nearly, if at all, the one is approached by the other.

II. The Case for Inconsequentiality

To come to Harberger, Schwartzman, and Leibenstein, their case for the inconsequentiality of welfare losses due to monopolistic pricing is too familiar to need any detailed replication here. Moreover, the chief question that I must raise about their methodology is already evident. Thus, Harberger and Schwartzman both calculate monopoly welfare losses simply by aggregating for different industries areas such as *ABC* in Figure 2. That is also Leibenstein's procedure, though beyond collating previous findings he limits himself to illustrative calculations. The procedure, to repeat, is also a valid one,

provided that the income elasticity of demand for every monopolized product and all cross elasticities of demand among such products are zero. Otherwise, however, the procedure is subject to error at diverse points; an error, moreover, which is difficult to gauge. The practical import of the Harberger, Schwartzman, and Leibenstein findings, therefore, is obscure.

But I have considered their methodology from a more or less conventional standpoint. Is their procedure not more defensible in terms of the Hotelling formula that they apply? That seems doubtful when we consider that Hotelling derives his formula simply by disregarding higher order terms in a Taylor expansion of the utility function. As he properly explains, the formula yields "an approximate measure when deviations from the optimum system are not great" (p. 253). While Harberger, Schwartzman, and Leibenstein consider deviations from the optimum represented by varying but often sizable divergencies of prices from costs, they apparently assume that the Hotelling formula still yields a good approximation. They could be right, but it is difficult to know that without further inquiry.

According to the Hotelling formula, furthermore, welfare losses resulting from a displacement from a competitive equilibrium, and hence optimum, amount in money terms to $\frac{1}{2}\sum dp_i dx_i$. Here dp_i and dx_i are the variations in p_i and x_i that the displacement entails. The summation is taken over all goods, though if, as here, one commodity is taken as numeraire, that necessarily drops out of the formula. Note, however, that dx_i is the change in the consumption of x_i that is induced by a change not only in the price of that good but in the prices of all other goods. Supposedly income also varies in a prescribed manner.[4] Hence complex demand effects of the sort I encountered above in the calculation of the NCV are also encountered here. As already indicated, such effects are nevertheless neglected by Harberger, Schwartzman, and Leibenstein.

Finally, Hotelling takes welfare losses to be represented in money terms by the quotient dU/α, where dU is the increment in utility and α is the marginal utility of money. For variations of any magnitude, however, welfare losses as so understood are unique only if the marginal utility of money is assumed constant. That was Marshall's assumption, but he would not have made it where prices are varying for products constituting a major part of the household's budget. Constancy in the marginal utility of money also entails a further assumption of cardinal measurability of utility, which Hotelling himself apparently preferred to avoid.[5]

[4] In his essay, Hotelling focuses on the impact of the introduction of excise in place of income taxes yielding the same total revenue. Since what counts is money income net of income taxes, the prescribed change in money income is evidently equal to the total revenue from the excise taxes, and so corresponds precisely to the MIA as defined here. As it turns out, that also means that the displacement from the optimum that Hotelling considers, like the one I consider, entails a shift along a plane in which consumption at predisplacement prices is constant. In my analysis, however, that occurs because of the assumption of a linear transformation locus. I find it rather puzzling, therefore, that Hotelling, pp. 255–56, apparently considers his formula as applying even where marginal costs are variable.

[5] Might we not, however, interpret α as representing simply the marginal utility of money at some intermediate point in the range in question, and so avoid in this way the assumption of constancy of the marginal utility of money? If we may judge from a recent discussion by Harberger (1971, pp. 786ff) of a formula similar to Hotelling's, he might now argue that α in the Hotelling formula be construed in just that way. But that apparently would mean that the term

$$(\alpha/2) \sum dp_i dx_i$$

which was derived as a lower order term in a Taylor's expansion, is nevertheless to be interpreted as the remainder term. How that may be done is not clear. Moreover, it is still disconcerting that the measure of welfare losses depends on an unknown point to which reference is made within the range in question. While Harberger applies the Hotelling formula without qualification, it should be observed that Schwartzman, p.

As seen by Harberger, Schwartzman, and Leibenstein, monopoly welfare losses evidently must turn primarily on two empirical factors: price elasticities of demand and price-cost ratios for monopolized products. That is still true according to the alternative methodology that I have elaborated, though Harberger, Schwartzman, and Leibenstein refer to own price elasticities, while as seen here cross and income elasticities also matter (and in the latter case, as seen from (7) and (9), not merely through the usual sort of income effects). It should be observed, therefore, that Harberger assumes throughout a price elasticity of unity for monopolized products. In his view,

> . . . one need only look at the list of industries . . . considered in order to get the feeling that the elasticities in question are probably quite low. The presumption of low elasticity is further strengthened by the fact that what we envisage is not the substitution of one industry's product against all other products, but rather the substitution of one great aggregate of products . . . for another aggregate. [1954, p. 79]

The assumption of a price elasticity of unity, however, was held "objectionable" by Stigler for the reason that "A monopolist does not operate where his marginal revenue is zero. . . . In any event, . . . most industries have long-run demand curves which are elastic" (p. 34). According to Schwartzman, Harberger's assumption is indeed to be thought of as applying to an industry rather than an individual firm: "Moreover, if we are interested in the value of resource misallocation by monopolistic industries as a group, the relevant demand elasticity is less than the average of the individual industry demand elasticities" (pp. 628–29). Schwartzman assumes the price elasticity of demand is no more than 2. For purposes of illustrative calculation, Leibenstein assumes that in monopolized industries the " . . . average elasticity of demand is 1.5" (pp. 395–96).

How elastic the demand for a composite of all monopolized commodities is in respect of price is an interesting question. But for purposes of appraising monopoly welfare losses, it is also not too relevant. All monopolized products could properly be treated here as a single composite product only if the prices of all such products exceed their competitive levels by relatively the same amount. So far as the facts are otherwise, welfare losses originate not only in inordinately high monopoly prices generally, but in the variation for different products in the relation of such prices to costs. Also, what counts is variation not only between industries in any conventional sense, but between products; even between different qualities or models of the same product (for example, different models of Buicks) so far as price-cost ratios vary here as well. In principle, therefore, welfare losses must be calculated by reference to the demand for each and every such monopolistic product, quality or model as the case may be. Only in that way can all such losses be allowed for.[6]

As to how elastic demand is for one or another product, quality or model, that

630, notes that he is neglecting variations in the demand for a product associated with changes in equilibrium magnitudes generally, as distinct from a change in the price of that product alone. He apparently considers such variations unimportant. Leibenstein does not refer to Hotelling, but he accepts Harberger's methodology. Leibenstein, p. 396, n. 3, refers, however, to the error due to neglect of income effects originating in the divergence of uncompensated from compensated demand schedules, and concludes that such effects are apt to be negligible. He may be right but as indicated income effects are seen here to be much more complex than he thus assumes.

[6] As explained, Harberger, Schwartzman, and Leibenstein all assume constant costs. In this essay, I have fallen in with that assumption, but note that so far as costs vary even uniform monopoly price-cost ratios would not mean that monopoly prices are all in the same relation to those that would prevail under competitive pricing.

must depend on the item. Presumably it also depends on the prices of other goods and household income. That is a matter of some importance, since in the calculation of gcv_i reference is to demand schedules which vary from item to item in respect of the levels at which prices of related goods and income are held constant. Any a priori assumption must be a gross oversimplification in this sphere, but I doubt that an elasticity of unity or even of 2 can be nearly large enough to encompass the interesting range of possibilities for the purposes of a calculation such as in question.

In this connection, it is pertinent to recall the relation familiar in monopoly theory that is alluded to by Stigler:

$$\overset{i}{\eta}_{xp} = p_i/(p_i - MC_i) \tag{10}$$

Here η^i_{xp} is the price elasticity of demand for the ith product, p_i is its price and MC_i, its marginal cost. No one supposes that (10) can be more than very broadly applicable to real world monoplies, but Leibenstein, for example, assumes a monopoly price-cost ratio of 1.2. It seems illuminating that with that ratio (10) would imply an elasticity of demand as high as 6. Leibenstein considers that the monopolistic price-cost ratios must in fact average less than 20 percent, but for a ratio of, say 10 percent, (10) yields an elasticity of 11. To repeat, though, (10) hardly applies exactly in practice, and it may be just as well to note here that I myself will allow later for possible divergencies from it in either direction. This assumption is in order when we consider such aspects as the limitations in a firm's knowledge of its cost and demand schedules; the fact that because of price leadership, collusion and other adaptations to oligopolistic interdependence the firm may calculate in terms of a demand schedule that is less elastic than the one relevant here (i.e., that where prices of all other products, including even close substitutes, are unchanged), and so on.

What of the price-cost ratios? Harberger deduced these from data on profit rates for different industries. Stigler, pp. 34–35, held, however, that monopoly profits are often capitalized, and in diverse ways not always sufficiently allowed for by Harberger, with the result that the indicated price-cost ratios may often be too low. Still other forces could operate to produce the same result. As Harberger is aware, monopoly prices reflect not only monopoly profits but monopolistic advertising, but, even for the early period he considers, the resulting additional misallocation cannot be dismissed as he dismisses it simply on the ground that advertising outlays were "... well under 2 percent of sales for all the industries ..." (1954, pp. 85–86) studied. The industries studied include competitive as well as monopolistic ones, so the corresponding ratio for monopolistic industries alone must be higher. What counts here, moreover, is not only average relations but their variation between industries and products.

Harberger treats intermediates as if they were consumers' goods. The relevant monopoly profits for any consumer's good, however, are not those prevailing in the industry in question, but those profits, together with the additional profits accruing on intermediate products used in that industry. That is so even though the concern is, as in the studies in question, only with misallocation between consumers' goods industries, and not with further losses due to monopolistic distortions in factor mixes. (I return to that later.) If, as a practical expedient, reference is to be made only to "direct" as distinct from "direct and indirect" monopoly profits, it should be closer to the mark to relate such profits to value-added rather than to sales, as Harberger does.

In his calculation Schwartzman seeks to determine the impact of monopoly on *U.S.* industrial prices from a comparison of ratios of sales and variable costs in similar concentrated and unconcentrated industries in the United States and Canada. In this way, the average "monopoly effect" is estimated at 8.3 percent of average variable costs. Schwartzman avowedly seeks to meet objections such as Stigler's to the Harberger calculation. To what extent he succeeds in doing so in his involved calculation is difficult to judge from his very brief exposition, and further questions such as were raised above regarding the Harberger calculation do not seem clearly disposed of. Schwartzman takes a step back from Harberger by assuming a uniform monopoly effect in all monopolized industries. He thus fails to allow for the misallocation due to variations in that effect between products. Monopoly price-cost ratios are a complex matter on which there will have to be many more studies before we can confidently narrow the possibilities.

I referred at the outset to a study of Kamerschen indicating that monopoly losses may be appreciably greater than Harberger and Schwartzman calculated. Kamerschen proceeds for the most part as Harberger did, so his findings too are difficult to construe, but he refers to profits data for a later period, 1956–57 to 1960–61. He also attempts to extend the calculations to embrace nonmanufacturing business and enterprises other than corporations, and to allow more systematically than Harberger could for capitalized monopoly profits and monopolistic distortions in costs in the form of intangible assets, royalties, and advertising expense. While intermediate products are again treated as final, however, monopoly profits are still related to sales rather than value added. Monopoly welfare losses are estimated at 1.03 to 1.87 percent of the national income depending on which of a number of variants is considered. These magnitudes, while modest, are, of course, far larger than Harberger's. They result from the assumption of a unitary elasticity of demand. Alternative calculations apparently assuming elasticities in different industries such as conform to (10) yield still much higher figures: 3.87 to 6.82 percent of national income.[7]

III. An Alternative Approach

In inquiring into the methodology of Harberger, Schwartzman, and Liebenstein, I have elaborated an alternative that is akin to theirs so far as monopoly welfare losses are still calculated from uncompensated demand schedules. But while the alternative methodology served as a basis for appraising that of Harberger, Schwartzman, and Leibenstein, it evidently must be difficult to apply when monopolized products are at all numerous. I now explore still another approach to the calculation of welfare losses due to monopoly pricing. Resting on the assumption of a special type of household indifference map, this approach can only yield hypothetical measures, but these may illuminate further what might already have been surmised: the marked sensitivity of the calculated welfare losses to the elasticity of demand for monopolized products and to the level and distribution of the monopoly price-cost ratios.

The household indifference map in question is given by equation (11):

$$(11)\quad U(x_1, \ldots, x_{n+1}) = \sum_{i=1}^{n+1} A_i x_i^{(1-1/\sigma)}$$

As before, I assume that there are $n+1$ industries producing a corresponding number of commodities, that of these industries one, $n+1$, is competitive and that all others are monopolistic. The output and

[7] I refer to calculations based on after-tax profits. Further calculations based on before-tax profits often yield even higher figures.

hence also the household's consumption of the ith good is x_i.

In (11), A_i is a constant, and so too is σ. If x_i stood for employment of a productive input rather than consumption, therefore, (11) would simply represent on the $x_1 \ldots x_{n+1}$ hyperplane a *CES* production function such as lately has become familiar in productivity analysis. The term σ would then represent the elasticity of substitution between any two factors, employment of all others being given.

I refer here nevertheless to consumption, but as Paul Samuelson, p. 787, has pointed out, the *CES* production function itself corresponds to a function of the same form that I derived long ago (1936, reprinted 1966) for a household's indifference map in an analysis of Ragnar Frisch's methods of measuring marginal utility. In any event, (11) may be conceived of as applying to consumption no less than to production, and for present purposes it has the distinct merit that by varying σ, now representing the elasticity of substitution between any two consumer's goods, we may allow different degrees of substitutability between products, and so ultimately for varying elasticities of demand for one or another of our monopolized goods. In the absence of empirical data on the comparative income elasticities of monopolized and competitive goods, it may be more of a virtue than a limitation of (11) that it implies unitary income elasticities of demand for all products alike.

While I shall refer to $U(x_1, \ldots, x_{n+1})$ as a utility function, our concern is only with the indifference map that the function defines. Where appropriate, utility might be envisaged as being represented by some function of $U(x_1, \ldots, x_{n+1})$, rather than by that function itself. The utility dimension, therefore, need not be representable by a linear homogeneous function such as is usually considered in productivity analysis. Even on that understanding, (11) is admittedly rather restrictive, but it still embraces an interesting range of possibilities. I use a function of the form of (11) here at the suggestion of Samuelson, who has also been helpful at other points.[8]

As before, the monopolized products, $x_1 \ldots x_n$, sell at prices $p_1 \ldots p_n$, which when fixed monopolistically have the values $p_1^m \ldots p_n^m$. The competitive good, x_{n+1}, serves as numeraire. I again designate by I^c the household's income as it would be if $x_1 \ldots x_n$ were to sell at competitive prices, $p_1^c \ldots p_n^c$, and there were no unemployment. Then

$$GCV = I^* - I^c \tag{12}$$

where

$$U(p_1^m, \ldots, p_n^m, I^*) = U(p_1^c, \ldots, p_n^c, I^c) \tag{13}$$

In other words, I^* is the income that the household would require if, when $x_1 \ldots x_n$ sell at $p_1^m \ldots p_n^m$, it is to enjoy the same utility as it would when $x_1 \ldots x_n$ sell at $p_1^c \ldots p_n^c$ and its income is I^c.

We also have

$$MIA = I^m - I^c \tag{14}$$

where I^m is the income that the household

[8] As he has also pointed out to me, the usual *CES* variant of (11), i.e., the one that is linear homogeneous, might itself be properly taken as a measure of real income. Moreover, for shifts along a linear production possibility schedule such as I have been assuming and will continue to assume here, real income as so understood and the net compensating variation turn out to be essentially the same metric. Thus, I express the *NCV* below as a coefficient, the decisive term being the ratio of two magnitudes of household income, one representing the income needed to assure, under monopoly pricing in monopolistic industries, the same utility as might have been enjoyed under competitive pricing in all industries, and the other representing simply the income needed to assure full employment under monopoly pricing in monopolistic industries. That ratio, as is not difficult to see, corresponds precisely to the ratio of real income in equilibrium under competitive pricing in all industries to real income in equilibrium under monopoly pricing in monopolistic industries.

must have if employment is to continue to be full when prices are $p_1^m \ldots p_n^m$ rather than $p_1^c \ldots p_n^c$. Finally,

$$(15) \quad NCV = (I^* - I^c) - (I^m - I^c) = I^* - I^m$$

While NCV is of interest, we may more readily relate our analysis to previous ones if I focus on a corresponding coefficient:

$$(16) \quad CNCV = (I^* - I^m)/I^m$$

In effect, this expresses the NCV as a fraction of the national income that would be produced in the full employment equilibrium under monopoly pricing.

If $x_i, i=1 \ldots n$, is measured in units such that $p_i^c=1$, production possibilities, which are again linear, are readily expressed in terms of a familiar formula convenient here:

$$(17) \quad \sum_{i=1}^{n+1} x_i = k$$

From (11), (16), (17) and the usual conditions for household equilibrium, it can be proven that:

$$(18) \quad CNCV = \left(\sum_{i=1}^{n+1} \gamma_i \lambda_i^{\sigma-1} \right)^{1/(\sigma-1)} \cdot \left(\sum_{i=1}^{n+1} \gamma_i \lambda_i^{-1} \right) - 1$$

Here, for $i=1 \ldots n$, λ_i is p_i^m when the unit of x_i is such that $p_i^c=1$, and also represents the monopolistic price-cost ratio. The term λ_{n+1} equals unity. Also,

$$(19) \quad \gamma_i = (p_i^m x_i^m)/I^m$$

or since $p_i^m=\lambda_i$

$$(20) \quad \gamma_i = \lambda_i x_i^m/I^m$$

where x^m represents the output of x_i when p_i, $i=1 \ldots n$ is fixed monopolistically, and there is full employment equilibrium, i.e., income is I^m. Thus γ_i is the income share that is accounted for in such an equilibrium by the household's expenditure on x_i. A proof of (18) is given in the Appendix.

From (18), the $CNCV$ depends on: (i) γ_i, the income share devoted to x_i, $i=1 \ldots n+1$, in the full employment equilibrium with monopoly prices; (ii) λ_i, $i=1 \ldots n$, the monopoly price-cost ratio for each and every product, it being understood that λ_{n+1}, the price-cost ratio for the competitive product, is unity; and (iii) σ the elasticity of substitution. In order to see how the $CNCV$ might vary in dependence on these parameters, let us consider first the case where there is but one monopolistic product, x_1, and the competitive product is accordingly x_2. Our parameters, then, consist simply of γ_1, λ_1, and σ. In Table 1, I show in percentages the magnitudes of the $CNCV$ indicated by alternative hypothetical values of γ_1, λ_1, and σ. In all cases, γ_1 is taken equal to 0.5, so the household divides its income equally between the monopolized and competitive products. For λ_1, the monopoly price-cost ratio, I consider three alternative values: 1.1,

Table 1—Values of the Coefficient of Net Compensating Variation ($CNCV$) for a Two-Good Economy and Alternative λ_1 and σ

[a] Shown in percent.

1.2, and 1.3. The elasticity of substitution, σ, varies between .50 and 64.[9]

The *CNCV* evidently varies widely in dependence on both these parameters. Thus, for $\lambda_1=1.1$, the *CNCV* varies from less than a tenth of a percent to 3.9 percent as σ varies from .50 to 64. For $\lambda_1=1.2$, the corresponding variation in *CNCV* is from two-tenths of a percent to 8.8 percent, and for $\lambda_1=1.3$, from four-tenths of a percent to 13.7 percent. For the single household economy in question, as indicated, reference in each case is in effect to the percentage relation of monopoly welfare losses to the national income. The *CNCV* is also affected by γ_1, though often not very markedly. Interestingly, depending on σ, a deviation of γ_1 in either direction from 0.5 may raise or lower the *CNCV*.[10]

Turning to many monopolized products, from the calculations just discussed, the *CNCV* evidently must depend on the average λ_i in monopolized industries. By merely increasing the number of monopolized products to two, we see that the *CNCV* is also sensitive to the distribution of λ_i about their mean.

Thus, in Table 2, I assume that there are two monopolized industries, x_1 and x_2, and one competitive one, x_3. The corresponding price-cost ratios are λ_1, λ_2, and λ_3, where $\lambda_3=1$. For the weighted mean of λ_1 and λ_2, we have

$$(21)\quad M_m(\lambda) = \left(\sum_{i=1}^{n} \gamma_i\lambda_i\right) \Big/ \left(\sum_{i=1}^{n} \gamma_i\right)$$

In the table, I consider, for $n=2$, three alternative values of $M_m(\lambda)$ corresponding to the three values of λ_1 that were considered previously, that is, 1.1, 1.2, 1.3. For each $M_m(\lambda)$ I refer to two variants, one in which λ_1 and λ_2 are distributed symmetrically about their mean, and the other in which their distribution about their mean is asymmetric, with λ_2 ex-

[9] Where $\sigma=1$, formula (11) gives way to the familiar Cobb-Douglas variant. In that case it is easy to show by reasoning such as is used to prove (18), that that formula is supplanted by:

$$CNVC = \left(\prod_{i=1}^{n+1} \lambda_i^{a_i}\right)\left(\sum_{i=1}^{n+1} a_i\lambda_i^{-1}\right) - 1$$

[10] For example, for $\lambda_1=1.2$, and σ taken in turn to be 2.0, 8.0, 16.0, and 46.0, I find that for $\gamma_1=.33$ the *CNVC* has these values: .74, 3.21, 6.19 and 11.37. For $\gamma_1=.67$, the corresponding figures are .74, 2.56, 4.04, and 5.98.

ceeding $M_m(\lambda)$ by more than λ_1 falls short of it. The specific λ_1 and λ_2 assumed in each variant are as indicated in the table. In all cases, γ_i for the competitive good—now γ_3—is 0.5, so as with the single monopolized good considered in Table 1, the two monopolized goods account for half the household's income. For the symmetric distributions, then, $\gamma_1=\gamma_2=0.25$. For the asymmetric distributions, $M_m(\lambda)$ is as assumed for $\gamma_1=.33$ and $\gamma_2=.17$.

With the inclusion of a second monopolized good in the economy the *CNCV* apparently increases markedly. That is so for all the assumed $M_m(\lambda)$ and for all the symmetric distributions of λ_1 and λ_2. It is even more so if λ_1 and λ_2 are distributed asymmetrically. For example, for $\sigma=8$, a monopoly price-cost ratio of 1.2 implied previously a *CNCV* of 3.2 percent. With a mean price-cost ratio for the two monopolized industries of 1.2, the *CNCV* now rises to 5.15 percent for the symmetric distribution. For the asymmetric distribution, the coefficient is still greater: 7.39 percent.

Further calculations assuming that the number of monopolistic products is indefinitely large but with price-cost ratios distributed in a more or less skew way, as might be expected, yield for a wide range of σ measures of the *CNVC* very similar to those obtained from the asymmetric distribution in Table 2.[11]

In selecting values of parameters for evaluation of the *CNCV*, I have tried to take account of related magnitudes considered in previous analyses, though I also refer to quite other possibilities as well, though perhaps not always very realistic ones. One of the parameters considered, however, is σ, the elasticity of substitution. That is, of course, not the same thing as the elasticity of demand considered in previous analyses, but for the utility function being considered the two aspects are related by a very simple formula:[12]

$$\eta^i_{xp} = \sigma - \gamma_i(\sigma - 1) \tag{22}$$

Here, η^i_{xp}, as before, is the negative of $(p_i/x_i)(\partial x_i/\partial p_i)$, the partial derivative being understood to have the usual sort of subscripts. Evidently, if $\sigma<1$, then $\eta^i_{xp}>\sigma$, but otherwise η^i_{xp} is no greater than σ, and is in fact less than σ whenever $\sigma>1$. The shortfall in the latter case is the greater the larger is σ and the larger is γ_i, the share of the commodity in question in the household's budget. While theoretically the divergence between η^i_{xp} and σ could thus be marked, presumably γ_i would tend to be small so far as there are many commodities. For practical purposes, therefore, η^i_{xp} should usually closely approximate σ, and my calculations may be read accordingly.

I have assumed that production possibilities are linear. That is more or less the counterpart of the assumption of constant costs made in previous analyses. Where costs are not constant but increasing, it has been held (see Harberger (1954, p. 82)) that other things equal, monopoly welfare losses will be less than where costs are constant. The appropriate translation of increasing costs here is a curvilinear production possibilities schedule that is concave from below. With such a schedule, the structural shift in outputs induced by

[11] The calculations assume as before that the competitive product accounts for one-half of income. The remaining half is distributed among monopolistic products on the assumption that the share of income represented by price cost ratios within a small interval $\Delta\lambda$ embracing any particular ratio λ is given by the product $\Delta\lambda$ and a linear function $\gamma(\lambda)=a\lambda+b$ which slopes downward to the right and reaches zero from above at $\lambda=h\equiv-(b/a)$. The constants a and b are evaluated so as to assure that $M_m(\lambda)$, the mean monopoly λ, corresponds to those considered previously: 1.1, 1.2, and 1.3. To cite one or two examples for $\sigma=8.00$ the *CNCV* for $M_m(\lambda)=1.1$ is 1.96; for $M_m(\lambda)=1.2$, 7.39; for $M_m(\lambda)=1.3$, 15.19.

[12] See the Appendix.

monopoly pricing is necessarily dampened, and one might suppose that as a result monopoly welfare losses would indeed be reduced. That could be so, but I believe it need not be. I leave this matter, however, to separate inquiry. Of course, so far as there is monopoly, we cannot at all exclude that in the vicinity of the equilibrium costs will be decreasing or that production possibilities will be convex from below.

I have also assumed that the elasticity of substitution is the same between any and all pairs of goods. As seen from (22) that need not mean that the elasticity of demand is also the same for all goods, but I have tacitly assumed that monopoly price-cost ratios might vary between goods independently of their price elasticities. As indicated, (10) can hardly be expected to apply systematically, but so far as it applies at all the price-cost ratios must in some degree vary inversely with price elasticities. Given that, one surmises that losses would be less than otherwise, but I leave this, too, to separate inquiry.

VII. Conclusions

I have sought to appraise calculations indicating that welfare losses due to monopoly pricing in a country such as the United States are relatively inconsequential, and have argued that those calculations are open to question on both conceptual and empirical grounds. Under an alternative approach, which does not seem subject to conceptual limitations affecting previous calculations, the coefficient of net compensating variation, which is taken to measure monopoly welfare losses, is quite sensitive to empirical aspects which still seem unsettled, particularly, the elasticity of demand for monopolized products, and the varying magnitudes of price-cost ratios for different monopolized products, together with the shares of household income that those products account for. While I have queried the conclusions of Harberger, Schwartzman, and Leibenstein, they have focused attention in a forceful way on an important question. That is a significant contribution in itself, from which nothing that has been said can detract.

I have joined previous writers in tacitly assuming that in the community considered, supplies of productive factors are given. No account has thus been taken of the adverse effect of monopolistic pricing on choices between leisure and work. The analysis can be extended in familiar ways to embrace such choices, however, so they seem to pose no new question of principle, though since leisure must be treated as a competitive good, its inclusion must affect the share of such goods in household income.[13]

I have also joined previous writers in focusing on welfare losses due to monopolistic pricing as that affects resource allocation as between consumer's goods. Monopolistic pricing, of course, also causes misallocation of resources at other points. Such further misallocation is properly the subject of a separate inquiry, but the calculations in question are sometimes taken to reflect monopoly welfare losses generally. Perhaps I should underscore, therefore, that whatever the losses due to misallocation between consumer goods, they are only compounded by misallocation caused by monopoly prices in other spheres, perhaps chiefly the determination of comparative factor proportions in different industries,[14] and the volume of saving and investment. Related to, but not the same thing as, misallocation due to monopoly pricing is the adverse impact of

[13] Monopolistic pricing also may have an adverse effect on effort, but at least in principle it is not difficult to extend the analysis to that aspect too.

[14] Harberger (1959) has tried to grapple with this matter, too, though reference is to distortions due to not only monopoly prices but other causes.

monopoly on the discovery and introduction of new technologies, though Schumpeter, of course, long ago made it a controversial matter whether monopoly is really always disadvantageous in this sphere. But the point being made is obvious and need not be labored: If consequential welfare losses due to monopoly are not precluded in respect of consumption structure, they hardly are so more generally.

Appendix

This appendix derives equations (18) and (22). To begin with (18), given (11) and that x_{n+1} is numeraire, we derive at once these equilibrium conditions for household consumption:

$$\text{(A1)} \quad U_i/U_{n+1} = (A_i/A_{n+1})(x_{n+1}/x_i)^{1/\sigma} = p_i, \qquad i = 1, \ldots, n$$

Here and elsewhere U_i, $i=1 \ldots n+1$, represents the marginal utility of x_i. Formula (A1) holds whether prices for monopolistic products, i.e., $x_i \ldots x_n$, are at competitive or monopolistic levels. But, given our choice of units for those products, $p_i^c = 1$, $i = 1 \ldots n$. Hence, when prices are at competitive levels and I is such as to assure full employment at those prices, the consumption of x_i and x_{n+1} conform to the relation:

$$\text{(A2)} \qquad \overset{c}{x}_i = (A_i/A_{n+1})^{\sigma} \overset{c}{x}_{n+1}$$

From this and (17),

$$\text{(A3)} \qquad \sum_{i=1}^{n+1} (A_i/A_{n+1})^{\sigma} \overset{c}{x}_{n+1} = k$$

It follows that

$$\text{(A4)} \qquad \overset{c}{x}_{n+1} = kA_{n+1}^{\sigma} \Big/ \sum_{i=1}^{n+1} A_i^{\sigma}$$

and

$$\text{(A5)} \quad \overset{c}{x}_i = kA_i^{\sigma} \Big/ \sum_{i=1}^{n+1} A_i^{\sigma}, \qquad i = 1, \ldots, n$$

When prices of monopolistic products are at monopoly levels, $\lambda_1 \ldots \lambda_n$, and money income is I^m, which assures full employment at these prices, we see by similar reasoning that the consumption of x_{n+1} is:

$$\text{(A6)} \qquad \overset{m}{x}_{n+1} = kA_{n+1}^{\sigma} \Big/ \sum_{i=1}^{n+1} \lambda_i^{-\sigma} A_i^{\sigma}$$

and of x_i,

$$\text{(A7)} \qquad \overset{m}{x}_i = k\lambda_i^{-\sigma} A_i^{\sigma} \Big/ \sum_{i=1}^{n+1} \lambda_i^{-\sigma} A_i^{\sigma}, \qquad i = 1, \ldots, n$$

Consider now the still different equilibrium that prevails when prices of monopolistic products are at monopoly levels, but money income is at I^*, as given by (13). Proceeding again much as before, we find that consumption of x_i and x_{n+1} conform to:

$$\text{(A8)} \qquad \overset{*}{x}_i = \lambda_i^{-\sigma} (A_i/A_{n+1})^{\sigma} \overset{*}{x}_{n+1}$$

In order to prove (18), I derive from the foregoing relations certain formulas for I^* and I^m. To refer first to I^*, we know that

$$\text{(A9)} \qquad I^* = \sum_{i=1}^{n+1} \lambda_i \overset{*}{x}_i$$

Also, as seen from (13),

$$\text{(A10)} \quad U(\overset{*}{x}_1, \ldots, \overset{*}{x}_{n+1}) = U(\overset{c}{x}_1, \ldots, \overset{c}{x}_{n+1})$$

From this and (11),

$$\text{(A11)} \quad \sum_{i=1}^{n+1} A_i (\overset{*}{x}_i)^{(1-1/\sigma)} = \sum_{i=1}^{n+1} A_i (\overset{c}{x}_i)^{(1-1/\sigma)}$$

Using this, (A2), and (A8),

$$\text{(A12)} \quad \overset{*}{x}_{n+1} = \overset{c}{x}_{n+1} \left\{ \sum_{i=1}^{n+1} A_i^{\sigma} \right\}^{\sigma/(\sigma-1)} \Big/ \left\{ \sum_{i=1}^{n+1} \lambda_i^{1-\sigma} A_i^{\sigma} \right\}^{\sigma/(\sigma-1)}$$

and

$$\text{(A13)} \quad \overset{*}{x}_i = \lambda_i^{-\sigma} (A_i/A_{n+1})^{\sigma} \overset{c}{x}_{n+1} \cdot \left\{ \sum_{i=1}^{n+1} A_i^{\sigma} \right\}^{\sigma/(\sigma-1)}$$

$$\Big/ \left\{ \sum_{i=1}^{n+1} \lambda_i^{1-\sigma} A_i^{\sigma} \right\}^{\sigma/(\sigma-1)}$$

From (A4), (A9), and (A13),

$$\text{(A14)} \quad I^* = k \left\{ \sum_{i=1}^{n+1} A_i^{\sigma} \right\}^{1/(\sigma-1)} \Big/ \left\{ \sum_{i=1}^{n+1} \lambda_i^{1-\sigma} A_i^{\sigma} \right\}^{1/(\sigma-1)}$$

Turning to I^m, we have

$$\text{(A15)} \quad I^m = \sum_{i=1}^{n+1} \lambda_i x_i^m$$

Using (A7),

$$\text{(A16)} \quad I^m = k \left\{ \sum_{i=1}^{n+1} \lambda_i^{1-\sigma} A_i^{\sigma} \right\} \Big/ \left\{ \sum_{i=1}^{n+1} \lambda_i^{-\sigma} A_i^{\sigma} \right\}$$

From (16), (A14), and (A16),

$$\text{(A17)} \quad CNCV = \left[\left\{ \sum_{i=1}^{n+1} A_i^{\sigma} \right\}^{1/(\sigma-1)} \left\{ \sum_{i=1}^{n+1} \lambda_i^{-\sigma} A_i^{\sigma} \right\} \Big/ \left\{ \sum_{i=1}^{n+1} \lambda_i^{1-\sigma} A_i^{\sigma} \right\}^{\sigma/(\sigma-1)} \right] - 1$$

From (A7) and (A16),

$$\text{(A18)} \quad \gamma_i \equiv (\lambda_i x_i^m / I^m) = \left(\lambda_i^{1-\sigma} A_i^{\sigma} \Big/ \sum_{i=1}^{n+1} \lambda_i^{1-\sigma} A_i^{\sigma} \right)$$

Formula (18) follows from (A17) and (A18).

While it may have been useful to prove (18) in the foregoing manner, it should be observed that the same result can be obtained somewhat more quickly if it is considered that from (16) the *CNVC* reduces to $(I^*/I^m - 1)$. Also, as given by (11) the utility function is homogeneous. Hence, equilibrium consumption positions relating to different levels of money income but the same prices all must be on the same ray through the origin. That is true particularly of the equilibrium consumption positions corresponding to I^* and I^m. It also follows that the ratio I^*/I^m corresponds to the comparative consumption of any one good in the two equilibrium positions. Given that, (18) follows from (A13), (A7), (A4), and (A16).

To come to (22), from (A1),

$$\text{(A19)} \quad p_j^{\sigma}(\partial x_j/\partial p_i) - (A_j/A_{n+1})^{\sigma} \cdot (\partial x_{n+1}/\partial p_i) = 0, \qquad j \neq i,$$

and

$$\text{(A20)} \quad p_i^{\sigma}(\partial x_i/\partial p_i) - (A_i/A_{n+1})^{\sigma} \cdot (\partial x_{n+1}/\partial p_i) = -\sigma p_i^{\sigma-1} x_i$$

In these formulas, the derivatives shown are of a partial sort; with appropriate subscripts understood. Also, since

$$\text{(A21)} \quad \sum_{i=1}^{n+1} p_i x_i = I,$$

we have

$$\text{(A22)} \quad \sum_{j=1}^{n+1} p_j(\partial x_j/\partial p_i) = -x_i$$

From (A19), (A20), and (A22),

$$\text{(A23)} \quad (\partial x_{n+1}/\partial p_i) = (\sigma - 1) A_{n+1}^{\sigma} x_i \Big/ \sum_{i=1}^{n+1} p_i^{1-\sigma} A_i^{\sigma}$$

And from this and (A20),

$$\text{(A24)} \quad (\partial x_i/\partial p_i) = \left\{ (\sigma - 1) A_i^{\sigma} x_i / p_i^{\sigma} \sum_{i=1}^{n+1} p_i^{1-\sigma} A_i^{\sigma} \right\} - \sigma x_i / p_i$$

or

$$\text{(A25)} \quad \eta_{xp}^{i} = \sigma - (\sigma - 1) p_i^{1-\sigma} A_i^{\sigma} \Big/ \sum_{i=1}^{n+1} p_i^{1-\sigma} A_i^{\sigma}$$

Formula (22) follows at once from (A18) for monopoly equilibrium where $\lambda_i = p_i$, but it is evident that it must hold for any other equilibrium as well, for in (A18) λ_i could be construed as well to represent any p_i, and not merely a monopolistic one.

Devaluation, Money, and Nontraded Goods

RUDIGER DORNBUSCH*

This paper develops a monetary approach to the theory of currency devaluation.[1] The approach is "monetary" in several respects. The role of the real balance effect is emphasized and a distinction is drawn between the relative prices of goods, the exchange rate and the price of money in terms of goods. Furthermore, money is treated as a capital asset so that the expenditure effects induced by a monetary change are spread out over time and depend on the preferred rate of adjustment of real balances.[2] The latter aspect gives rise to the analytical distinction between impact and long-run effects of a devaluation.

The first part of this paper develops a one-commodity and two-country model of devaluation. The simplicity of that structure is chosen quite deliberately to emphasize the monetary aspect of the problem as opposed to the derivative effects that arise from induced changes in relative commodity prices. Trade is viewed as the exchange of goods for money or a means of redistributing the world supply of assets. A devaluation is shown to give rise to a change in the level of trade and the terms of trade, the price of money in terms of goods.

In the second part the implications of the existence of nontraded goods are investigated, and induced changes in the relative prices of home goods enter the analysis.

I. Devaluation in a One-Commodity World

In this part we develop a purely monetary approach to devaluation in discussing a two-country, two-monies, and one-commodity model.[3] This stripped down model abstracts from the complexities of distribution and substitution effects that may arise from changes in relative commodity prices and places primary emphasis on the real balance effect.

A. *The Model*

We assume that money is the only marketable asset and that real income (output) is in fixed supply in each country. The demand for nominal balances in each country is assumed to have the Cambridge form.[4]

* University of Rochester. This paper draws on my dissertation and I am indebted to the members of my thesis committee, Harry Johnson, Stanley Fischer, and Robert Mundell. In revising the material I had the benefit of comments from Karl Brunner, George Borts, Stanley Engerman, and Murray Kemp. I am particularly indebted to Ronald W. Jones and Michael Mussa with whom I enjoyed extended discussion of the topic.

[1] This approach is by no means novel. For formal developments see Frank Hahn, Jones (1971), Kemp (1969, 1970), Mundell, and Takashi Negishi (1972). Acceptance of that approach has nevertheless remained limited.

[2] A "capital-theoretic" approach to the real balance effect is developed by Alvin Marty.

[3] The notion of trade in one commodity may alternatively be interpreted as trade in a composite commodity, so that relative goods prices remain unchanged. Such conditions may obtain either because of perfect substitution or else because of the absence of distribution effects.

[4] The particular functional form of the demand for money obviously lacks generality. It is chosen here in order not to detract from the main line of argument. Alternative specifications would assume the demand for money proportional to expenditure as in Jones (1971) or else derive the demand for money from intertemporal utility maximization. Provided the underlying utility function is separable in consumption and real balances the qualitative conclusions of this paper carry over to such a formulation.

$$(1) \qquad L = kP\bar{y}; \qquad L^* = k^*P^*\bar{y}^*$$

where

k, k^* = the desired ratios of money to income
$\bar{y}, \bar{y}^*$ = real outputs
P, P^* = the money price of goods in terms of domestic and foreign currency

and where an asterisk denotes the foreign country. Given the exchange rate, e, the domestic currency price of foreign exchange, arbitrage ensures that

$$(2) \qquad P = P^*e$$

With respect to monetary policy we assume that the nominal quantity of money in each country M, M^*, is initially given and that governments abstain from changing domestic money supplies except as it is necessary to maintain a pegged exchange rate. Accordingly the rate of increase in the domestic money supply is given by the trade balance surplus, B.

$$(3) \qquad \dot{M} = B = -e\dot{M}^*$$

Desired nominal expenditure in each country, Z, Z^*, is equal to money income less the *flow* demand for money, H, H^*, where the latter is assumed proportional to the *stock* excess demand

$$(4) \qquad Z = P\bar{y} - H$$
$$Z^* = P^*\bar{y}^* - H^*$$

$$(5) \qquad H = \pi(L - M) = H(P, M);$$
$$H^* = \pi^*(L^* - M^*) = H^*(P^*, M^*)$$

and where π and π^* are the domestic and foreign rates of adjustment. The expenditure functions in (4) imply a short-run marginal propensity to spend out of income smaller than unity while in the long-run, when monetary stock equilibrium is attained, the average propensity to spend equals unity.

In Figure 1 we show the domestic rate of hoarding, H, and the foreign rate of *dis*hoarding, $-H^*$, as a function of P the domestic currency price of goods. The schedules are drawn for given nominal money supplies in each country and an exchange rate e^0. With the nominal quantity of money given, hoarding in the home country is an increasing function of the price level. An increase in the price level creates a stock excess demand for money and causes expenditure to decline relative to income as the community attempts to restore the real value of cash balances. It follows that we may view the hoarding schedule alternatively as the flow demand for money or the excess supply of goods (in nominal terms). By the same reasoning the foreign rate of *dis*hoarding, given the exchange rate, is a decreasing function of the home price level. We note that the distribution of the money supplies underlying Figure 1 is not compatible with balance of payments equilibrium. Foreign monetary stock equilibrium would obtain at P' while for domestic monetary equilibrium the price level would have to be equal to P''.

Consider now the conditions of short-run equilibrium. In order for the world goods market to clear, we require that world income equal world expenditure or

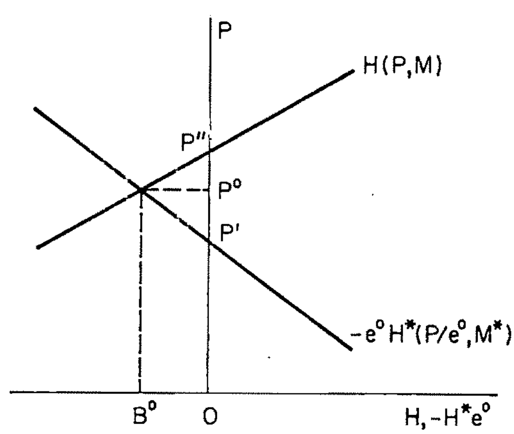

FIGURE 1

equivalently that the home country's rate of hoarding equal the foreign country's rate of dishoarding.

$$H = -H^*e^0 \tag{6}$$

The equilibrium is shown in Figure 1 at a domestic currency price of goods P^0; a higher price level would leave a world excess supply of goods and a lower price level a world excess demand for goods. We observe, too, that the short-run equilibrium at P^0 implies a trade balance deficit for the home country equal to B^0. That deficit, in the absence of sterilization, as we assume, redistributes money from the home country to the rest of the world. The reduction in the domestic nominal quantity of money reduces real balances at the initial price level and thereby causes planned hoarding to decrease and conversely abroad. In terms of Figure 1 this implies that the hoarding and dishoarding schedules shift to the right, a process that continues over time until they intersect between P'' and P' on the vertical axis. At that time exchange of money for goods ceases since each country has achieved its preferred asset position and spends at a level equal to its income.

B. *The Short-Run Effects of a Devaluation*

Consider now the short-run or impact effect of a devaluation on the part of the home country. A devaluation changes the equilibrium relationship between price levels in the two countries. Differentiating equation (2) we obtain

$$\hat{P} = \hat{P}^* + \hat{e} \tag{7}$$

where a ˆ denotes a relative change in a variable. Equation (7) informs us only about the relationship between changes in the price levels at home and abroad; we have to investigate the equilibrium condition in the world goods market in order to determine what the actual change in the price level in each country will be. For that purpose we turn to Figure 2 where we show the world economy in initial long-run equilibrium at a domestic currency price of goods P^0.

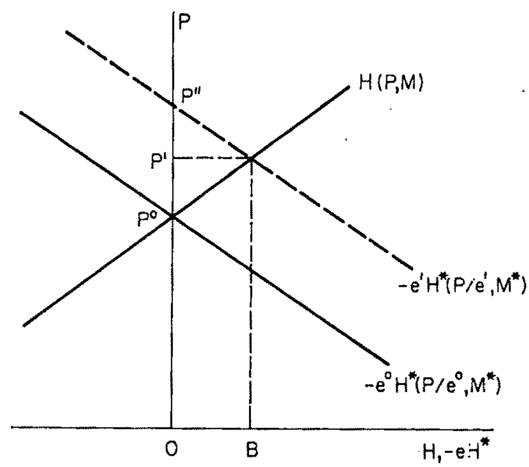

FIGURE 2

The effect of a devaluation is shown in Figure 2 by an upward shift in the foreign dishoarding schedule. For foreign monetary stock equilibrium to obtain, given the nominal quantity of money, the foreign currency price of goods would have to remain constant which in turn by (7) implies that the domestic price level would have to increase in the same proportion as the exchange rate, a price change equal to $(P''-P^0)/P^0$. The domestic hoarding schedule, on the contrary, is unaffected and domestic monetary stock equilibrium would continue to obtain at a domestic price level P^0. It is observed from Figure 2 that at an unchanged domestic price level there would be a world excess demand for goods due to the increase in foreign real balances and expenditure while at an unchanged foreign price level there would be a world excess supply of goods due to the decrease in domestic real balances and expenditure. It follows that in order for the world goods market to clear the price level changes will have to

be distributed in such a manner as to reduce domestic absorption and increase foreign absorption by an equal amount.

The equilibrium increase in the domestic price level is equal to $(P'-P^0)/P^0$ while the foreign price level declines in the proportion $(P''-P^0)/P^0$. We note that both the domestic and foreign currency price of goods change less than proportionately to the rate of devaluation and that the distribution of price changes depends on the relative slopes of the hoarding schedules.

Given these price changes foreign real balances have increased and the real value of domestic balances has decreased thereby causing foreigners to dishoard in order to decumulate their capital gains and domestic residents to save in order to restore the real value of their cash balances. The home country's balance of payments surplus is equal to OB and causes a redistribution of the world money supply.

The formal criterion for the price changes and the balance of payments can be developed by differentiating the goods market equilibrium condition

$$(6') \quad \pi(kP\bar{y} - M) + e\pi^*(k^*P\bar{y}^*/e - M^*) = 0$$

with respect to P and e holding the nominal quantity of money constant in each country. The relative change in the domestic price level is

$$(8) \qquad \hat{P} = \frac{\pi^*M^*e}{\pi M + \pi^*M^*e}\,\hat{e}$$

Defining the world money supply, measured in terms of domestic currency $\overline{M}$,

$$(9) \qquad \overline{M} = M + eM^*$$

and the domestic and foreign country's share in the money world supply, σ and σ^*, we can rewrite (8) as

$$(8') \qquad \hat{P} = \frac{\pi^*\sigma^*}{\pi\sigma + \pi^*\sigma^*}\,\hat{e} \geq 0$$

Substituting (8′) in (7) we obtain the effect of a devaluation on the foreign price level:

$$(10) \qquad \hat{P}^* = \frac{-\pi\sigma}{\pi\sigma + \pi^*\sigma^*}\,\hat{e} \leq 0$$

Equations (3′) and (10) show the distribution of price changes to depend on relative effective size where effective size is the product of the speed of adjustment and the share in the world money supply. In the small country case ($\pi\sigma/\pi^*\sigma^*=0$) the home country price level increases in the same proportion as the exchange rate.

The home country's trade balance surplus is obtained by differentiating the flow demand function for money with respect to the price level and substituting (8) to yield

$$(11) \quad dB = dH = \pi M\left[\frac{\pi^*M^*e}{\pi M + \pi^*M^*e}\right]\hat{e} > 0$$

Equation (11) confirms that the balance of payments unambiguously improves.

C. *The Long-Run Effects of Devaluation*

The long-run effects of devaluation on nominal money supplies and price levels may be interpreted with the help of Figure 3. In quadrants II and IV we show the domestic and foreign demand for real balances as hyperbolae; quadrant III shows the equilibrium price relationship $P^*e=P$ for the initial exchange rate as the ray OA. Lastly in quadrant I the world money supply at the initial exchange rate is given by $\overline{M}\overline{M}^*$, where $\overline{M}^*=\overline{M}/e$.

Initial long-run equilibrium is indicated by point E where the distribution of the world money supply is such that each country holds the desired quantity of real balances and where the equilibrium relationship between price levels is satisfied.[5]

A devaluation on the part of the home

[5] For a similar geometric treatment, see Arnold Collery.

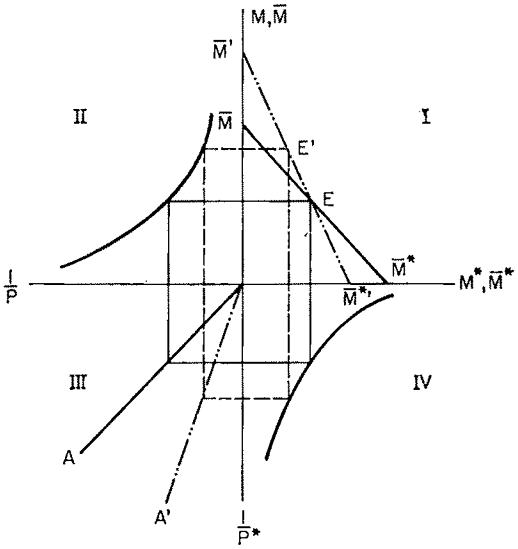

FIGURE 3

country affects both the price relationship and the world money supply. To each domestic price level corresponds now a lower equilibrium foreign price level; this is indicated in quadrant III by a rotation of the arbitrage line to OA'. Furthermore, given the initial nominal quantities of money in each country indicated by point E, the world money supply measured in terms of either currency changes: it decreases when measured in terms of foreign currency by the initial domestic quantity of money times the exchange rate change and it appreciates in terms of domestic currency by the initial foreign quantity of money times the exchange rate change. Accordingly the world monetary constraint rotates around point E—the initial endowment of currencies—to become $\overline{M}'\overline{M}^{*\prime}$.

It is readily verified from Figure 3 that the initial distribution of money supplies at point E is no longer appropriate as a long-run equilibrium position since it would be inconsistent with the new price relationship. The new long-run equilibrium is shown by point E' indicating an increased domestic quantity of money and price level and a decreased foreign quantity of money and price level. Real balances obviously remain unchanged, between the new equilibrium and the old.

We should emphasize that our assumption about the absence of national money supply changes other than by the balance-of-payments mechanism is only one possible assumption about the behavior of money supplies. If we had assumed on the contrary that the home country accompanied the devaluation by an equiproportionate increase in its nominal quantity of money the only short- and long-run effect of the combination of policies would be an equiproportionate increase in the domestic price level and no effect whatsoever abroad.[6]

The latter monetary assumption would be appropriate if the home country wished to run a transitory budget deficit financed by money creation without impairing its foreign exchange position; the former assumption corresponds to the case where a country uses a devaluation to increase its foreign exchange holdings.

II. Devaluation and Nontraded Goods

In this part we consider an extension of the monetary model to introduce flexibility in relative prices. Following Jones (1972), Michael Michaely, Mundell, and Anne Krueger, we assume that there are two classes of goods produced and consumed in each country, traded goods and nontraded goods. Each class of goods itself is taken to be a composite commodity so that the relative prices of goods within each group are invariant. The aggregation chosen here places emphasis on the relative price of nontraded in terms of traded

[6] In terms of Figure 3 the policy combination would imply that the world monetary constraint both rotates and shifts outward passing through $\overline{M}^*$ since the world money supply measured in terms of foreign currency would remain unchanged. The conclusions in the text are readily verified from the fact that the new equilibrium point would lie vertically above point E.

goods rather than on the terms of trade between internationally traded goods; it emphasizes the effects of changes in absorption on relative prices rather than the income effect of changes in the relative prices of traded goods.

This extension has two implications for the effects of a devaluation: changes in hoarding or equivalently changes in expenditure relative to income change the equilibrium relative price of home goods and these changes in relative prices in turn affect the equilibrium rates of hoarding.

We will show that in this more disaggregated structure the conclusions of the one-commodity model continue to hold for the effects of a devaluation on the balance of payments and the prices of traded goods; the additional element that arises is that the reduction in domestic absorption and the increase in foreign absorption cause the relative price of home goods to decline at home and to rise abroad. This result may be viewed as a special case of transfer analysis and arises in that perspective since each country's marginal propensity to spend on foreign home goods is by definition zero.[7]

A. *The Model*

Denoting traded and nontraded commodities as goods one and two, respectively, we assume that production takes place along a concave transformation curve and that supplies are a function only of the relative price:

$$X_i = X_i(q) \qquad i = 1, 2 \tag{12}$$

where q is the relative price of nontraded goods—the ratio of the domestic currency prices of nontraded and traded goods, P_2 and P_1, respectively:

$$q = P_2/P_1 \tag{13}$$

Demand for the two commodities is assumed to depend on money prices and nominal expenditure, or, using the homogeneity property and adopting traded goods as a numeraire, on relative prices and real expenditure measured in terms of traded goods, $\tilde{Z}$.[8]

$$C_i = C_i(q, \tilde{Z}) \qquad i = 1, 2 \tag{14}$$

Real expenditure is defined as real income less real hoarding, all measured in terms of traded goods as a numeraire:

$$\tilde{Z} = \tilde{Y} - \tilde{H} \tag{15}$$

where real income or the real value of output is defined as follows:

$$\tilde{Y} \equiv X_1 + qX_2 = \tilde{Y}(q) \tag{16}$$

Monetary considerations affect the goods markets via the expenditure function and in particular via the planned rate of hoarding. Maintaining our assumption that the demand for nominal balances is proportional to money income and that hoarding is proportional to the stock excess demand for money we may write the desired real rate of hoarding, measured in terms of traded goods, as a function of the relative price and the real quantity of money measured in terms of traded goods:

$$\tilde{H} = \tilde{H}(q, \tilde{M}) \tag{17}$$

where

$$\tilde{M} = M/P_1 \tag{18}$$

Our assumptions about the stock demand for money ensure that an increase in either domestic currency price raises the desired rate of real hoarding so that the following properties hold:

$$q\frac{\partial \tilde{H}}{\partial q} \equiv \alpha > 0; \qquad -\tilde{M}\frac{\partial \tilde{H}}{\partial \tilde{M}} \equiv \beta > 0 \tag{19}$$

[7] The relationship between the transfer problem and devaluation is more extensively analyzed in Dornbusch (1973) and Jones (1971).

[8] In the remainder of this paper a tilde will denote the fact that a quantity is measured in terms of traded goods. When these quantities are referred to as "real" this will not imply measurement in terms of a price index.

The definition of real expenditure in (15) may be rewritten as the budget constraint in a manner that reveals the disaggregation of the model:

$$(20)\quad q(X_2 - C_2) + (X_1 - C_1) = \tilde{H}$$

It is evident from the budget constraint that when the home-goods market clears ($X_2 = C_2$) the excess supply of traded goods identically equals the planned rate of hoarding.

Given a corresponding set of behavioral relations and constraints for the foreign country we can now turn to the conditions of short-run equilibrium in this model. Short-run equilibrium obtains when for a given exchange rate and given money supplies, all goods markets clear; that is, when the market for nontraded goods clears in each country and when the world market for traded goods clears. Such an equilibrium, by the budget constraint in each country, implies that one country's planned rate of hoarding equals the other country's planned rate of dishoarding. Equations (21) formally state these equilibrium conditions of the model

$$(21)\qquad \begin{aligned} E_2 &\equiv X_2(q) - C_2(q, \tilde{Z}) = 0 \\ E_2^* &\equiv X_2^*(q^*) - C_2^*(q^*, \tilde{Z}^*) = 0 \\ &\tilde{H}(q, \tilde{M}) + \tilde{H}^*(q^*, \tilde{M}^*) = 0 \end{aligned}$$

where

$$\tilde{M}^* \equiv M^*/P_1^*; \qquad q^* \equiv P_2^*/P_1^*; \qquad P_1^* e = P_1$$

The first two conditions in (21) state that in equilibrium the excess demand for home goods is zero in each country while the third equation is the market clearing condition in the market for traded goods.

B. *The Impact Effect of a Devaluation*

To examine the modifications in the effects of devaluation brought about by the introduction of nontraded goods we consider first the relationship between the relative price of home goods and real hoarding. In particular we want to show that an increase in real hoarding lowers the relative price of home goods. That result obtains since an increase in real hoarding represents a decrease in real expenditure relative to real income so that at constant relative prices and given a positive marginal propensity to spend on home goods the demand for home goods decreases. A decline in the relative price of home goods is required in order to eliminate the excess supply generated by an increase in hoarding. More formally the relationship between the relative price of home goods and real hoarding may be derived by differentiating the first market equilibrium condition in (21) to obtain

$$(22)\quad \hat{q} = -\frac{m_2}{(\eta_2 + e_2)qC_2}\, d\tilde{H}$$

where

$$m_2 \equiv q\frac{\partial C_2}{\partial \tilde{Z}} > 0$$

$$\eta_2 \equiv -\frac{q}{C_2}\left[\frac{\partial C_2}{\partial q} + \frac{\partial C_2}{\partial \tilde{Z}}\,\frac{\partial \tilde{Y}}{\partial q}\right] > 0$$

$$e_2 \equiv \frac{\partial X_2}{\partial q}\,\frac{q}{X_2} > 0$$

The terms m_2, η_2, and e_2, denote respectively, the marginal propensity to spend on home goods, the compensated elasticity of demand for home goods, and the elasticity of supply.

In Figure 4 we show the market equilibrium schedule for the home country's nontraded goods market as the locus $E_2 = 0$; to maintain market equilibrium the expenditure reducing effects of an increase in hoarding have to be offset by the substitution effects of a decrease in the relative price of home goods.

So far we have treated hoarding as the exogeneous variable and have enquired into the relative price effects of changes in

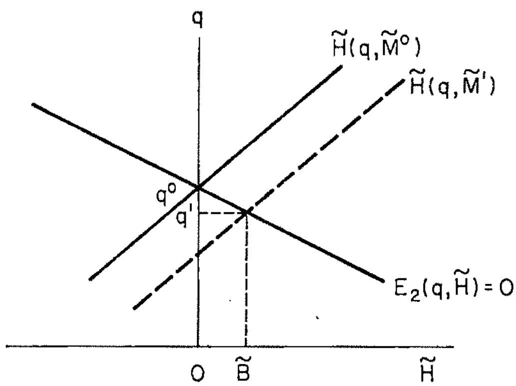

FIGURE 4

hoarding. We wish next to develop an expression that relates the rate of hoarding, given the nominal quantity of money, to price changes. Differentiating the hoarding function in (17) we obtain

$$d\tilde{H} = \alpha\hat{q} + \beta\hat{P}_1 \tag{23}$$

and substituting for the change in the relative price of home goods, $\hat{q}$, from (22), we obtain

$$d\tilde{H} = \gamma\beta\hat{P}_1 \tag{24}$$

where the terms

$$\gamma \equiv \frac{1}{1 + \alpha\delta} > 0; \qquad \delta \equiv \frac{m_2}{(\eta_2 + e_2)qC_2} > 0$$

are introduced for notational convenience. To gain further understanding of the relationship between hoarding, relative prices and the money price of traded goods derived in (24) we turn to Figure 4 where we show the effect of an increase in the price of traded goods. In addition to the market equilibrium schedule for home goods we draw a hoarding schedule as an increasing function of the relative price of home goods, given the nominal quantity of money and the price of traded goods and hence the real quantity of money, $\tilde{M}^0$. The schedule is upward sloping since an increase in the price of home goods raises income and hence the demand for money thereby increasing the desired rate of hoarding.

Initial equilibrium is shown at a relative price of nontraded goods, q^0. An increase in the price of traded goods reduces the real money supply and hence increases at constant relative prices the desired rate of hoarding. This is shown in Figure 4 by a rightward shift of the hoarding schedule. Since at constant relative prices there is an excess supply of home goods, their relative price will decline to q' which in turn dampens the equilibrium rate of hoarding, $\tilde{B}$, relative to what it would have been at constant relative prices. The shift in the hoarding schedule corresponds to the term $\beta\hat{P}_1$ in (24) while the dampening effect shows in the term γ.

It will be recognized that in the composite commodity model analyzed earlier perfect substitutability ensured that $\delta=0$. In the present formulation the absence of perfect substitution and the requirement that home-goods markets clear ensure that absorption changes are reflected in changes in relative prices; furthermore these induced changes in relative prices affect the equilibrium rate of hoarding tending to reduce the hoarding response associated with a given change in the price of traded goods.

Having developed the basic relationships of the model we can now proceed to investigate the effects of a devaluation. For that purpose we turn to Figure 5. In the upper part of that figure we draw the domestic and foreign home goods market equilibrium schedules, where the latter is drawn as a function of the foreign rate of *dis*hoarding and hence is negatively sloped. We assume, arbitrarily and without consequence, that initially the relative prices of home goods are the same in both countries. In the lower part of Figure 3 we draw the domestic hoarding schedule and the foreign dishoarding schedule. It is important to note that along these hoarding schedules the relative price of home goods

is allowed to adjust in order to clear the home-goods market so that by the budget constraint these hoarding schedules may alternatively be interpreted as the domestic excess supply of traded goods and the foreign excess demand for traded goods. Analytically the schedules are defined by equation (24) and its counterpart for the foreign country.

Initial equilibrium obtains at a domestic currency price of traded goods P_1^0 and equilibrium relative prices of home goods $q^0=q_0^*$. A devaluation by the home country may be analyzed in a manner similar to the composite commodity model developed above. At an unchanged domestic currency price of goods foreign real balances increase causing foreigners to dishoard which is shown in Figure 5 by a

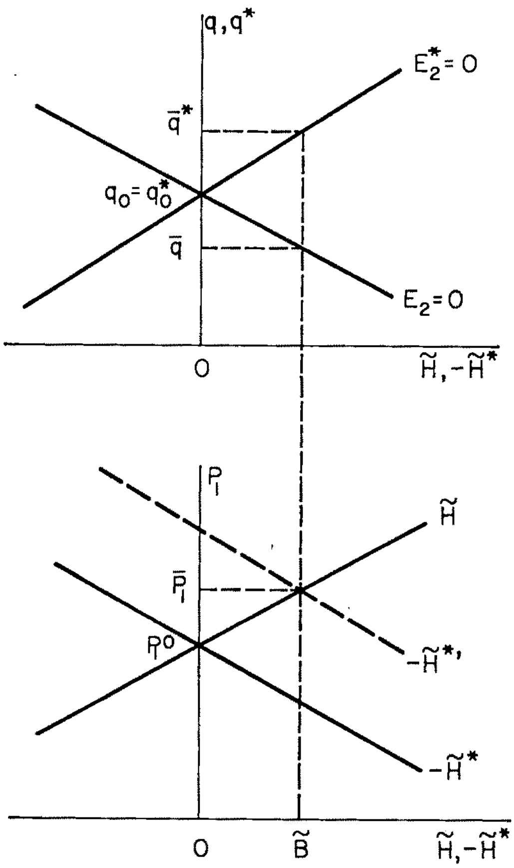

FIGURE 5

rightward shift of the foreign dishoarding schedule to $\tilde{H}^{*\prime}$. Short-run equilibrium will obtain at a domestic currency price of goods $\bar{P}_1$ where the world market for traded goods clears. The increase in the domestic price of traded goods causes the home country to reduce expenditure relative to income and run a trade balance surplus equal to $\tilde{B}$. Corresponding to the reduction in domestic absorption we find a decline in the relative price of nontraded goods at home to $\bar{q}$ while the increase in foreign absorption raises the relative price of nontraded goods in that country to $\bar{q}^*$.

These results can be derived more formally by consideration of the equilibrium in the world market for traded goods. Recalling that (24) allows explicitly for market clearing in the home-goods market that expression is identically equal to the excess supply of traded goods. Accordingly we may use (24) and its counterpart for the foreign country to determine the effects of a devaluation on the domestic currency price of traded goods:

$$(25)\quad \beta\gamma\hat{P}_1 + \beta^*\gamma^*(\hat{P}_1 - \hat{e}) = 0 = d\tilde{H} + d\tilde{H}^*$$

Solving for the relative change in the domestic currency price of traded goods yields

$$(26)\qquad \hat{P}_1 = \frac{\beta^*\gamma^*}{\beta\gamma + \beta^*\gamma^*}\,\hat{e} \equiv \theta\hat{e}$$

The solution for the effect of a devaluation on the domestic currency price of traded goods shows that this price will increase less than proportionately to the rate of devaluation $(0<\theta<1)$. Differentiating the price relationship $P_1^*=P_1/e$ it is seen that the foreign currency price of traded goods will fall less than proportionately to the rate of devaluation. Substitution of (26) in (24) shows that the devaluing country's balance of payments unambiguously improves:

$$(27)\qquad d\tilde{H} = \beta\gamma\theta\hat{e}$$

So far our results correspond qualitatively to those obtained in the composite commodity model. The departure arises from the fact that changes in absorption in the two countries change the equilibrium relative prices of home goods. Substituting (27) in (22) we find that a devaluation lowers the relative price of nontraded goods in the home country and raises it abroad:

$$(28) \quad \hat{q} = -\delta\beta\gamma\theta\hat{e}; \quad \hat{q}^* = \delta^*\beta^*\gamma^*(1-\theta)\hat{e}$$

While, like in the first part of this paper, short-run equilibrium is characterized by an exchange of traded goods for real balances and hence the absorption effects of a devaluation are emphasized, the role of the relative price of home goods is nevertheless crucial in the adjustment mechanism. Given imperfect substitutability between home goods and traded goods on the production side it is the adjustment in the relative price of home goods that translates changes in absorption into an excess supply of traded goods at home and an excess demand for traded goods abroad.

III. Concluding Remarks

Rather than summarize here the conclusions of this paper we wish to emphasize some of the issues raised by the present formulation of devaluation analysis.

The first and primary issue concerns the role of money in models of devaluation. The stance taken here is that a devaluation is foremost a monetary phenomenon and that its effects derive from the reduction in the real value of money attendant upon a devaluation. If it is believed that the effects of a reduction of real balances on expenditure, by whatever transmission mechanism, are negligible then it may stand to reason that the effects of a devaluation are negligible not that there must be other powerful avenues through which it exerts its effects.

The second issue that deserves attention is that of aggregation. The formulation developed here suggests that it is helpful to view traded goods as a composite commodity and thus to highlight the distinction between money and goods and between classes of goods that are respectively traded and nontraded.

The Effect of the EEC and EFTA on European Trade: A Temporal Cross-Section Analysis

By NORMAN D. AITKEN*

Utilizing a cross-sectional trade flow model of the type developed by Hans Linnemann and Jan Tinbergen, this study attempts to isolate empirically the major forces which have shaped European trade relations over the period 1951–67. We first estimate via the use of dummy variables the impact of the European Economic Community (*EEC*) and the European Free Trade Association (*EFTA*) on member trade. For each year of the European integration period (1959–67), a cross-sectional equation is estimated and used to test for the existence and approximate size of the respective integration effects. The equation is also calculated for the eight years prior to the integration period to obtain a clear picture of the forces which were at work before the formation of the *EEC*. Secondly, a base year equation is used to make projection estimates of the gross trade creation and European trade diversion effects of the two communities.

I. Methodology

As defined by Bela Balassa (1967, p. 5), gross trade creation (*GTC*) will refer to the total increase in trade among members of a trading community brought about through integration, regardless of whether the additional trade replaces domestic production or whether it replaces nonmember exports. The substitution of imports from member countries (higher cost imports) for imports from nonmember countries (lower cost imports) will constitute trade diversion (*TD*). External trade creation (*ETC*) will refer to integration-caused increases in trade between a trading community and countries outside the trading community. *ETC* as an effect of economic integration is possible in the case of a customs union where high tariff countries have to reduce their tariffs to the outside world as a part of the process of achieving a common external tariff. *ETC* minus *TD* yields the net effect of a trading bloc on the outside world.

All empirical studies which have attempted to measure integration effects have been faced with the common problem of isolating the effect of integration on trade from the effect of income growth and changes in other variables which normally affect international trading patterns. The major approaches to this problem have either been to examine changes in market share of imports (or apparent consumption)[1] or to incorporate income directly into the statistical analysis (by

* Associate professor of economics, University of Massachusetts. Research for the paper was supported in part by a grant from the Research Council of the University of Massachusetts. I am indebted to Ronald Ehrenberg, Bradley Gale, James Kindahl, Joseph Kushner, Laurence Mauer, Anthony Scaperlanda, George Treyz, Brendan Walsh, anonymous referees, and the editor for valuable comments on earlier drafts of the paper. I assume all responsibility for any errors that remain.

[1] Various formulations of the market-share approach are used in the studies by Edwin Truman, P. S. Verdoorn, and F. J. M. Meyer Zu Schlochtern, J. Waelbroeck, M. K. Carney, and The European Free Trade Association (1969).

calculating income elasticities of import demand for the pre- and postintegration periods[2] or by using income as an independent variable in a trade-estimating model).[3] Both of these approaches attempt to measure the effects of integration indirectly, or in other words as a residual. Either by using a base year trade matrix or a base period relationship between income and imports, estimates are made of what trade would have been in the absence of economic integration and these estimates are then compared to actual trade to obtain the trade preference effect. One is thus left with the uncertainty as to whether or not other factors may have been responsible for the difference between projected and actual values. Furthermore, the residual approach does not provide an objective basis for determining the first year in which integration effects occurred. The base periods selected by previous studies of the *EEC* range from 1958 to 1961 and hence it is clear that there is no general agreement as to the timing of the first *EEC* effect on trade.

The present study has attempted to deal with these problems by estimating, through the least squares regression method, the following variant of the Linnemann trade flow model for each year of the 17-year period 1951–67.

$$(1)\quad \log X_{ij} = \log b_0 + b_1 \log D_{ij} + b_2 \log Y_i + b_3 \log Y_j + b_4 \log N_i + b_5 \log N_j + b_6 \log A_{ij} + b_7 \log P_{ij}^{EEC} + b_8 \log P_{ij}^{EFTA} + \log e_{ij}$$

where X_{ij} is the dollar value of country i's exports to country j measured according to country j's import data, Y_i and Y_j are the nominal GNP of countries i and j expressed as a dollar value, N_i and N_j are the populations of the respective countries, D_{ij} is the distance between the commercial centers of the two countries, A_{ij} is a dummy variable for adjacent or neighboring countries, P_{ij}^{EEC} and P_{ij}^{EFTA} are dummy variables for trade between partners of the *EEC* and *EFTA*, respectively, and *log* refers to common logarithms.[4]

The variables Y_i and N_i together determine the potential export supply of country i, with Y_i determining economic capacity and N_i determining the domestic market/foreign market production ratio. (N determines market size and, assuming economies of scale, the larger N the more lines of production for which the country will meet the minimum market size for efficient market production (see Linnemann, pp. 11–14). The larger N, therefore, the larger the domestic market to foreign market ratio and the smaller the potential export supply of the country.) The variables Y_j and N_j together determine the potential import demand for country j, using the same arguments that were applied to potential export supply. D_{ij} is a proxy variable for natural trade resistence which in turn is a composite of transportation cost, transport time, and economic horizon. Consequently, D_{ij} along with N_i and N_j is hypothesized to have a negative effect on X_{ij}.

Neighboring countries (A_{ij}) can be expected to have an additional stimulus to trade because of similarity of tastes and an awareness of common interests (see Balassa (1961, p. 40)). Perhaps more important, however, neighboring countries are likely to experience significant additional amounts of international trade in

[4] Sources of data: *Direction of Trade; Distance Between Ports; EFTA Trade: 1969; International Financial Statistics; National Accounts of OECD Counties;* and *Monthly Bulletin of Statistics.* Values of 2 and 1 were used for the three dummy variables to indicate the presence and absence of the given characteristic. A mimeographed data appendix is available from the author.

the form of what are essentially locally traded goods, especially where border regions are densely populated as in much of Europe.[5]

The use of this model permits us to incorporate into the analysis as independent variables the preference area effects through the use of dummy variables. Dummy variables are used to represent in an approximate way phenomena which are difficult to measure. The approximate nature of the trade preference variables means that their measured effect on trade flows must in turn be considered approximate. On the other hand, there are distinct advantages to the use of the cross-sectional model.

First, by estimating the preference effect as an independent variable in a multiple regression equation one is able to hold constant other major variables which affect trade, including not only potential demand and supply but also to some extent the effects of general changes in trade liberalization and transportation cost. Changes in the latter over time would tend to be picked up by the proxy variables D_{ij} and A_{ij}. (The proxy variables themselves, of course, do not change over time, but changes in the real variables would be expected to show up as changes from year to year in the estimated coefficients of the proxy variables.) Specifically, since the size of the trade-stimulating effect of European trade liberalization may be expected to vary inversely with distance (natural trade resistance) the effect of trade liberalization may show up as a change over time in the D_{ij} or A_{ij} coefficients or both.

In addition, the use of a cross-sectional model allows the estimation of trade preference coefficients for each year in the integration period and hence a series of parameter estimates can be obtained which can then be considered as a whole in terms of whether their pattern indicates the expected cumulative growth in the preference effects.

The preference parameters can in turn be used to estimate the dollar value of *GTC* for each of the two European communities. Because the estimates for each year are derived from the cross-sectional equation for that year, each estimate is independent of the others and the estimating procedure does not require the use of a base year. In fact, the results of the study provide information which may be useful in determining when the first integration effects on trade occurred.

Using the trade-preference coefficients to estimate the trade-stimulating effect of integration in any postintegration year requires one to assume that the size of the coefficient is being determined solely by the effect of the trade preference and therefore that it is not in part reflecting some other special trade relationship which had existed in the preintegration period. Consequently, it will be necessary to test the preference coefficients for nonsignificance in the preintegration period as well as for significance in the postintegration period. By calculating the equation for the eight years preceding the first tariff reductions of the *EEC*, we were thus able to test for

[5] Equation (1) represents what Tinbergen has labeled a "turnover equation" in which prices are not specified (see Linnemann pp. 4, 47 for a detailed discussion of this point). Variables which explicitly measure artificial trade barriers are also absent from the equation because of the overwhelming statistical and methodological problems associated with their direct measurement (Linnemann, p. 30). The exclusion of these variables from the equation could be expected to seriously bias the trade preference coefficients only if there were a high correlation between the excluded variables and the trade preference variables themselves. If a high correlation existed, however, it would show up in the form of significant or near significant trade preference coefficients in the preintegration years. Since, as will be seen below, the preintegration preference coefficients are consistently insignificant, it seems reasonable to assume that the preference variables are not highly correlated with any important variable that has been excluded from the statistical analysis.

the existence of preintegration preference effects.

The sample from which the equations were calculated includes the original seven *EFTA* members plus the five *EEC* trading countries (Belgium-Luxembourg being one trading country).[6] The sample thus contains 20 trade flows between *EEC* partners, 42 trade flows between *EFTA* partners, and 70 trade flows between the members of the two trade blocs for a total of 132 observations per year. The 70 trade flows between the two blocs are assumed to constitute "normal" European trade and it is against these normal trade flows that trade among members of the respective communities is tested for preferential effects.[7] Clearly, this assumption would be invalid for any year in which trade flows between the two blocs have, on the average, experienced significant amounts of *TD*.[8] Previous studies, however, have found little or no net trade diversion by either bloc. But rather than rely on the findings of previous studies, it was decided to test for the existence of *TD* between the two blocs by the following procedure: The cross-section regression results were examined to find an appropriate base year free of integration effects. The equation for the base year was then used to estimate what trade would have been between the two blocs in subsequent years had there been no integration in Europe. A comparison of the projection estimates with actual trade provides an estimate of the degree to which trade between the two blocs has been reduced as a result of trade diversion. The projection approach was also used to estimate gross trade creation within the *EEC* and *EFTA* as a further check on the dummy variable estimates. Consequently, the second part of the statistical analysis consists of residual estimates of the dollar value of gross trade creation and trade diversion, but they are residual estimates based on the information provided by the regression results as to the timing of the first *EEC* effect on European trade. Furthermore, the assumption of normal trade between the *EEC* and *EFTA* should be considered only as an initial working hypothesis to be tested against the projection estimates before any conclusions are reached concerning the general magnitude of *GTC* within the two trading communities.

II. Empirical Results

A. *Regression Results*

Table 1 contains the estimated parameter values for the trade flow equation for the 17-year period 1951–67. The trade

[6] See Table 3 for a listing of the individual countries. Finland was excluded from the sample because its late entry into *EFTA* meant that its inclusion in the sample would have made it more difficult to discern the first *EFTA* effect on the original members.

[7] The decision to limit the sample only to members of the two trading communities may be open to question. Ideally, one would prefer to have "normal trade" represented by the exports of both *EFTA* and *EEC* members to countries who are not members of either bloc. Within Western Europe, however, only less developed countries fall into the nonmember category and the possibility of having normal trade represented by trade flows to the developed countries outside of Europe was rejected because a significant proportion of the observations on normal trade would have occupied extremely high points on the regression lines with respect to the independent variables, while all intra-*EEC* and intra-*EFTA* observations would have been in the lower range. It was concluded, therefore, that a sample limited to the specified European countries would provide the greatest opportunity for obtaining bias-free preference coefficients in the preintegration years and hence that one would obtain the most sensitive measure for identifying both the timing and general magnitude of the preference effects. The fact that trade flows between the two blocs had to be used to represent normal trade precluded the introduction of additional dummy variables to measure the potential trade diversion effect (*TD*) of each bloc against the other.

[8] The existence of *TD* would lead to an inflated estimate of *GTC* since the value of the trade preference coefficients would tend to be increased by an integration-caused reduction in the average trade flow between the two blocs as well as by an integration-caused increase in the average trade flow among members. It should be noted, however, that while the existence of *TD* could lead to an inflated estimate of *GTC*, it could not result in the finding of a *GTC* effect where none exists since by definition *TD* cannot occur unless *GTC* occurs as well.

[a] X_{ij} is the dependent variable; all variables are expressed in *logs*; *t*-values shown in italics, where 1.66 and 2.36 are significant at the .05 and .01 level, respectively.

preference coefficients come very close to fitting the expected theoretical pattern. In all the preintegration years (1951–58) the P^{EEC} coefficient is not significantly different from zero and even has a negative sign.[9] In 1959, the first year of integration, there is a sharp increase in the value of the coefficient (at least relative to earlier years) as the coefficient becomes positive

[9] Despite the consistent negative sign in the preintegration years there is a small perceptible movement in the P^{EEC} coefficient in 1957 and 1958. This small movement could be reflecting the effect of any of a number of different underlying factors, including the French devaluation, the European Coal and Steel Community, or a possible lagged effect of European trade liberalization. It seems unlikely, however, that any of these factors could have been responsible for the large changes in the coefficient which occur during the integration period. Since rapid progress was made in the liberalization of intra-European trade during the early 1950s (see Robert Triffin, ch. 5, and the *OEEC*, pp. 31–32), one would expect the resulting trade stimulation to be reflected in the regression equations during the early years of the study period. The A_{ij} coefficient exhibits a definite increasing trend from 1951 through 1957 after which it tends to stabilize at around 0.8 until near the end of the study period where it shows another small increase in value. The behavior of the A_{ij} coefficient, therefore, is more consistent with the expected timing and magnitude of intra-European trade liberalization than is the smaller and later preintegration movement of the P^{EEC} coefficient.

for the first time. The value of the coefficient continues to increase in subsequent years, reaching a significance level of .1 in 1960 and becoming statistically significant at the .05 level in 1961. The change in sign and large change in value of the P^{EEC} coefficient (relative to earlier years) from 1958 to 1959 is consistent with the hypothesis that the first *EEC* effect on member trade occurred in 1959, but the hypothesis of no *EEC* effect cannot be rejected at the standard .05 confidence level until 1961.[10] In dealing with the methodological issue of selecting a base year for making projection estimates, however, the appropriate methodological question is not whether the null hypothesis of no *EEC* effect can be rejected at the .05 level, but rather whether or not the hypothesis of no *EEC* effect can be accepted. To make the latter decision, the hypothesis to be tested for acceptance (i.e., no *EEC* effect) becomes the alternative hypothesis and the hypothesis that the *EEC* has had a positive effect on trade becomes the equivalent of the null hypothesis (i.e., the hypothesis to be tested for rejection). Clearly, the positive P^{EEC} coefficients for 1959 and 1960 and the change in sign and large increase in value from 1958 to 1959 do not permit the rejection of the hypothesis of a positive *EEC* effect and hence the hypothesis of no *EEC* effect cannot be accepted for those years. The year 1958, therefore, constitutes the last date for which the regression results allow one to assume that there was no *EEC* effect on member trade.[11]

The coefficient for the *EFTA* preference area follows a pattern similar to that of the *EEC*. In the preintegration years (1951 through 1959) the coefficient is insignificant and in all but the first year it carries a negative sign. In 1960, the first year of integration, the sign is still negative, but since the tariff reductions took place in July of that year, there would have been very little time for the new tariff levels to affect trade flows. The coefficient becomes positive (although it is extremely small) in the following year, grows slowly through 1963, and becomes statistically significant (.05 level) in 1964. The behavior of the P^{EFTA} coefficient is thus consistent with the hypothesis that the first *EFTA* effect on trade took place in 1961, although the null hypothesis of no *EFTA* effect cannot be rejected at the .05 confidence level until 1964.[12] All the other estimated parameters in the equations have the correct sign and all are significant at at least the .05 level in every year.

[10] The standard t-test for the significance of the coefficient constitutes only part of the statistical evidence which should be considered in evaluating the null hypothesis for 1959 and 1960, since it does not take into consideration all the information provided by the total set of yearly regression results. A runs test on the yearly sign of the P^{EEC} coefficient for the 17-year period yields a probability of .00008 that the sign pattern could have occurred by chance. A test of the sign of the yearly change in the value of the coefficient, to test whether or not the coefficient is changing in a random manner, gives $P>.97$ that the coefficient is changing in a random manner for the preintegration period (1951–58), but $P<.001$ (ten consecutive increases) for the integration period (1958–67).

[11] Studies which have used a base year beyond 1958 assume that the *EEC* could not have affected trade in 1959 and/or 1960 either because the 1959 tariff cuts were extended to all *GATT* members or because of an assumed lag in the response of firms to the tariff reductions. The 1959 internal tariff cuts of the *EEC*, however, were specified in the Treaty of Rome, signed in March 1957, while the decision to extend the 1959 tariff reductions to non-*EEC* members was made by the Council of Ministers only on Dec. 3, 1958. Furthermore, the extension of the 1959 tariff reductions to *GATT* members was subject to the important proviso that no tariff would be reduced below the eventual common external tariff (*CET*) for the product. Since the tariffs of Germany and the Benelux countries were already below the *CET*, the tariff reductions to other *GATT* members were limited, for the most part, to French and Italian imports. (See the *Three Banks Review*.) It is by no means clear, therefore, that there could not have been an *EEC* effect on member trade as early as 1959 and certainly the question is not above empirical investigation.

[12] $P=.0007$ that the sign pattern of the P^{EFTA} coefficient could have occurred by chance. $P>.92$ that the coefficient is changing in a random manner for the preintegration period (1951–59); $P<.01$ that change is random during the integration period.

B. *Dummy Variable and Projection Estimates*

The trade preference coefficients provide a measure of the factor by which normal trade among members has been increased as a result of the formation of *EEC* and *EFTA*. Estimates of *GTC* for each trading community, therefore, can be derived from the coefficients for each year of the respective integration periods.[13] These estimates are presented and discussed below in conjunction with the projection estimates.

As noted above, 1958 is the last year for which it can safely be assumed that there was no *EEC* effect on European trade. Accordingly, 1958 was selected as the base year for making the projection estimate of what trade would have been in the absence of economic integration.

In order to make the projections, the 1958 equation was recalculated leaving out the two trade preference variables and the following results were obtained:

$$(2)\quad \log X_{ij} = 1.978 - \underset{(3.76)}{.487} \log D_{ij} + \underset{(8.33)}{1.062} \log Y_i + \underset{(5.75)}{.733} \log Y_j - \underset{(3.36)}{.459} \log N_i - \underset{(1.90)}{.259} \log N_j + \underset{(2.84)}{.718} \log A_{ij} + \log e_{ij}$$

$$\bar{R}^2 = .776 \qquad S.E. = .289$$

The t-values are all significant above the .05 level.[14]

Equation (2) cannot account for the trade effects of changes in competitive position among the countries in the sample[15] nor can it account for any general trade liberalization effects which may have occurred after 1958. The projection estimates are made, therefore, on the basis of the usual assumption that the effect of these factors on trade has been small relative to the effects of integration. For the estimation of *GTC*, this assumption is supported by the regression results of the present study, where the pronounced increase in the trade preference coefficients indicates that economic integration provided the major impetus for additional trade (with the effect of income held constant) among the respective members of the two blocs. For trade between the two blocs, however, the model cannot provide information as to the general magnitude of the *TD* (or *ETC*) effect.

The exponential form of equation (2) was used to estimate intra- and inter-*EEC* and *EFTA* trade and the estimated trade values were then subtracted from actual trade to obtain the residual estimates of the trade effects of the *EEC* and *EFTA*. Since equation (2) estimates the dollar value of trade in 1958 prices, estimated trade was multiplied by country i's export

[13] Since raw data values of 1 and 2 were used for the dummy preference variables, $2^{\hat{b}_7}$ provides an estimate of the factor by which the average trade flow among *EEC* members has been increased as a result of integration. Actual intra-*EEC* trade divided by $2^{\hat{b}_7}$, therefore, yields an estimate of what intra-*EEC* trade would have been in the absence of integration. This value in turn, is subtracted from actual trade to obtain the estimated *GTC* of the *EEC* for the given year.

[14] The error term was included in the equation because the cross-section residuals tended to be stable over time. Real *GNP* in 1958 prices was used to make the projection estimates since it provided the best measure of how the economic capacity of each country has changed relative to the base year. A detailed explanation of these points is provided in an extended mimeographed copy of the paper.

[15] The fact that there was significant dispersion in the export price trends of the individual countries within each trading community over the projection period (see *International Financial Statistics*, Aug. 1968, p. 30) means that the projection estimates for each country are likely to be subject to error, but it also means that there will be at least some tendency for the errors to cancel out in the aggregate results for each community as a whole (i.e. not all competitive effect errors will be in the same direction). Consequently, less confidence can be placed in the individual country estimates than in the aggregate community results. Even in the latter case, however, the results should be considered only as indications of approximate magnitude.

[a] Estimates of Gross Trade Creation (*GTC*).
[b] Estimates of the net external trade creation (*ETC*) or trade diversion (*TD*) effect of the *EEC* on the exports of *EFTA* countries.
[c] Estimates of the net *TD* effect of *EFTA* on the exports of *EEC* countries.
[d] Dummy variable estimates of *GTC* derived from the P^{EEC} and P^{EFTA} coefficients reported in Table 1.
[e] Actual trade in current prices minus trade estimated by equation (2) converted to current prices.
[f] Zero values are given for 1959 and 1960 since the P^{EFTA} coefficient is negative for those years.

price index (dollar prices, 1958 base) in order to obtain estimates of the effects of integration in current prices.[16] The projection estimates therefore can be compared directly with the dummy variable (*DV*) estimates which reflect the prices of the given year for which the regression equation was calculated. The projection estimates for each of the four subgroupings of the sample are contained in Table 2 along with the *DV* estimates of *GTC*.

Because the economic integration of both trading communities has been a cumulative process (i.e., internal tariffs being reduced by stages over the integration periods covered by the study), one should expect to find the estimates of *GTC* increasing from year to year with no reversals. Both the *DV* and projection estimates of the respective communities' effect on member trade are consistent with this expectation. For the *EEC*, the projection estimates are consistently below the *DV* estimates, with the gap increasing at the end of the study period. Despite this discrepancy, both estimates show a large *EEC* effect occurring in 1959 and a strong cumulative growth in the yearly values of *GTC*. For *EFTA*, both estimates also show a cumulative growth in *GTC*, but the *DV* estimates are below (but reasonably close to) the projection estimates through 1962. Starting in 1963, however, the *DV* estimate is greater, with the gap increasing progressively in subsequent years. Even if allowance is made for a large margin of error, the results clearly indicate that the *GTC* of the *EEC* has been substantially greater than that of

[16] The use of total export price indexes introduces error into the results since composition of exports to the *EEC* and *EFTA* may differ from total export composition (although each country's exports to the respective trading communities would, in general, cover a broad spectrum of its total commodity exports).

EFTA. In percentage terms, the projection estimate of *GTC* accounts for 38 percent of actual intra-*EEC* trade (import data) and 16 percent of total *EEC* exports in 1967. For *EFTA*, the projection estimate of *GTC* for 1967 accounts for 16 percent of intra-*EFTA* trade and only 4 percent of total *EFTA* exports.

In considering the effects of each trading community on the other, *EFTA* could only be expected to have a negative effect on *EEC* exports since there was no reduction in the external tariffs of *EFTA* countries. Furthermore, the size of the *TD* effect should increase progressively throughout the integration period since increasing trade discrimination against nonmembers would result from the progressive reduction in internal tariffs. The estimated *EFTA* effect on *EEC* exports, therefore, is only partially consistent with theoretical expectation. The fact that the estimated net effect becomes negative in 1961 (the first full year of integration) and the existence of increasing negative values through 1964 is consistent with the *TD* hypothesis, while the indicated reduction in the size of the *TD* effect during the last three years of the period is not. Disaggregation of the *EFTA* effect on *EEC* exports by individual *EFTA* importing country revealed that the decrease in the "*TD* effect" over the specified period was accounted for almost entirely by the United Kingdom, with the net effect on *EEC* exports increasing from −\$38 million in 1963 to \$530 million in 1967. Since the period 1964–67 coincides with the general decline in the *U.K.* balance of trade position culminating in devaluation at the end of 1967, the divergence of the *U.K.* effect can be attributed to the serious deterioration of the *U.K.* competitive position. The net effect on *EEC* exports of all *EFTA* countries other than the United Kingdom over the same period was found to be consistent with the expected increasing *TD* effect (the estimated net *TD* effect increased progressively from −\$223 million in 1963 to −\$731 in 1967).

Because of the reductions in external tariffs by the original high tariff *EEC* countries (i.e., France and Italy), both *ETC* and *TD* are theoretically possible effects of the *EEC* on *EFTA* trade. The *TD* effect would be expected to dominate eventually, however, since the reduction of internal tariffs toward zero would eventually result in trade discrimination against nonmembers, even in the markets of the original high tariff countries. The estimates of the net *EEC* effect on *EFTA*, therefore, are not inconsistent with theoretical expectation, since they show a general increasing net *ETC* effect through 1963,[17] followed by the emergence of a growing net *TD* effect over the last three years of the period.

Finally, the fact that *TD* is dominating trade between the two communities over the latter years of the period explains the growing divergence between the *DV* and projection estimates for these years. It can be concluded, therefore, that the *DV* estimates are definitely inflated for the years 1965–67 and possibly for earlier years as well. Hence, the *DV*-estimates must be rejected in favor of the projection estimates for at least the last three years of the period.

C. *Individual Country Estimates*

Having found that the results for the two trading communities as a whole are consistent with theoretical expectation, we now proceed to the question of whether the expected results hold for each of the individual countries in the sample for the

[17] Disaggregation of the *EEC* effect by original high and low tariff *EEC* countries provided additional support for the *ETC* hypothesis since the results showed that the increasing *ETC* effect for the period 1959–63 was entirely accounted for by the original high tariff *EEC* countries.

TABLE 3—NET EFFECT OF *EEC* AND *EFTA* ON 1967 TRADE OF INDIVIDUAL COUNTRIES—PROJECTION ESTIMATES

(Millions of Dollars at Current Prices)

Exporting Country	Net *EEC* Effect	Net *EFTA* Effect

United Kingdom	245	− 2
Total *EFTA*	−629	1264

last year of the study period.[18] This represents a more stringent test of the *GTC* and *TD* hypotheses, since there is less opportunity for errors caused by competitive effects to cancel out in the estimates for the individual countries than there is in the aggregated community results. Table 3 contains the individual country projection estimates for 1967. Because of the possibility of error, inter-country comparisons in the size of the estimated effects should be avoided. The results should be viewed primarily in terms of whether or not they are consistent with the *GTC*, *TD*, or *ETC* hypotheses.[19] With the exception of the small negative value for the United Kingdom, the estimated effects of the *EEC* and *EFTA* on the trade of the respective member countries are all positive and hence consistent with the expected *GTC* effect. (Again, the discrepancy for the United Kingdom can be attributed to the deterioration of the *U.K.* competitive position.)[20]

The estimated net *EEC* effect on the individual *EFTA* countries indicates that all *EFTA* countries other than the United Kingdom were experiencing net *TD* as of 1967.

Disaggregation of the 1967 *EFTA* country estimates by original high and low tariff *EEC* countries showed that the high tariff countries accounted for $238 million of the total *EEC* effect on the United Kingdom and hence the positive effect for the United Kingdom can be attributed to *ETC*.[21] Sweden ($82 million) and Switzerland ($7 million) also showed evidence of an *ETC* effect by the high tariff *EEC* countries, but it was more than offset by a much larger *TD* effect from the low tariff countries.[22] Consequently, the results indicate that while *TD* was the dominant effect of the *EEC* towards *EFTA* in 1967, the three major industrial countries of *EFTA* continued to benefit from *ETC* in the French-Italian market.

The estimated *EFTA* effect on *EEC* countries shows positive values for both France and Italy which are contrary to theoretical expectation, since only a *TD* effect could be expected.[23] While it is pos-

[18] Copies of individual country estimates for earlier years are available from the author.

[19] Because of the large magnitude of the difference in *GTC* estimates between the respective members of the two communities, it is possible to conclude that the *GTC* of each *EEC* member has been greater than the *GTC* of any *EFTA* member.

[20] The estimated *EEC* effect on each of the five member countries was positive for all years of the period 1959–67 and the estimated *EFTA* effect on each of the seven member countries was consistently positive after 1962 with the exception of the United Kingdom in 1967.

[21] While *ETC* by France and Italy explains virtually all of the positive *U.K.* value for 1967, the fact remains that there is no evidence of a net *TD* effect by the low tariff *EEC* countries against the United Kingdom as of 1967. (This was true for earlier years as well.) This finding is surprising in view of the fact that *TD* and the worsening *U.K.* competitive position should both be operating to produce a negative effect.

[22] A net *TD* effect by both high and low tariff *EEC* countries prevailed in the case of the four remaining—less industrialized—countries of *EFTA*.

[23] The net effect of all *EFTA* countries other than the United Kingdom was as follows: Belgium-Luxembourg (−131), France (230), Germany (−539), Italy (125), Netherlands (−416). Consequently, while the removal

sible that these two countries experienced only minimal *TD* by *EFTA*, one certainly cannot rule out the possibility that the estimates may have been largely influenced by competitive effects. Consequently, while the net effect of *EFTA* on the *EEC* as a whole is consistent with the *TD* hypothesis, there are sufficient discrepancies among the individual country estimates to temper this conclusion with reservation.

III. Summary and Conclusion

The empirical findings of the study were found to be generally consistent with the expectations of customs union theory. The results showed that both the *EEC* and *EFTA* have experienced a cumulative growth in *GTC* over their respective integration periods, with the *GTC* of the *EEC* being substantially greater than the *GTC* of *EFTA*. The projection estimates for 1967 placed the size of the *GTC* effect for the *EEC* and *EFTA* at approximately \$9.2 billion and \$1.3 billion, respectively. The estimated effect of *EFTA* on the *EEC* as a whole showed a consistent *TD* effect for the period 1961–67, but there were two positive deviations from the expected negative effects of *EFTA* on the exports of the five individual *EEC* countries. The *EEC* was found to have had a net *ETC* effect on *EFTA* through 1964, but this was replaced by a growing net *TD* effect from 1965 through 1967. The estimated effects of the *EEC* on both member-country trade and *EFTA*-country exports were found to be consistent with theoretical expectation.

The regression results of the study yielded the important methodological conclusion that 1958 is the last year for which it can safely be assumed that European trade was unaffected by the formation of the *EEC*. This finding, in turn, suggests that an underestimation of the *EEC* effect on member trade could result if a base year beyond 1958 is used to represent normal preintegration trade.

of the United Kingdom from the *EFTA* effect moves the estimates more in line with the *TD* hypothesis, positive values still remain for France and Italy.

Black-White Differences in Returns to Schooling

By FINIS WELCH*

Investments in schooling in the United States have earned high returns in the aggregate, but at the same time estimated returns to blacks have been low. This paper updates previous estimates, showing that underlying the low averages reported for cross-sections of the black population there is a strong upward drift. Returns to blacks schooled in the 1920's and 1930's were so low that relative to whites, black income fell as school completion levels rose. Recent evidence shows, on the other hand, that returns, as a fraction of earnings, for blacks schooled in the 1950's and 1960's exceed returns to whites. These estimates imply that income gains that were earlier realized by whites as average educational levels increased are now being realized by blacks.

I. Earlier Estimates

In 1967, I observed that to a southern rural black, schooling was a poor investment, "A non-white with no schooling will receive 81 percent of the income of a similar white. Yet, for non-whites, school attendance increases income at a rate which is only 28 percent of the corresponding increases for whites" (p. 235). This estimate was based on the 1960 Census for earnings in 1959. Relative earnings of around 80 percent for blacks with no schooling, fall to less than 50 percent for college graduates. Using the same data, Giora Hanoch observed that " . . . internal rates of return for Non-whites are generally low and relatively erratic . . . " (p. 325), and William Landes estimated that outside the South, schooling returned only about 20 percent as much to nonwhites as to whites.

These are three of several income studies showing similarly pessimistic results, that the educational route to economic and social mobility was apparently closed to blacks. More recently this cloud of pessimism has been expanded to hover over quality of schooling as well. Christopher Jencks and his coauthors argue that family background factors dominate measures of academic achievement, leaving little room for attributes of schools to have an effect. And in any case, measured academic achievement (as distinguished from years of attendance) has little effect upon earnings. That this link between school traits and income is twice filtered through the screen of measured achievement seems not to matter. This, even though Herbert Gintis, one of Jencks' coauthors, has argued that existing achievement tests are capable of explaining only between 10 and 20 percent of the observed earning power of schooling. The view offered here is no more direct than that of Jencks. I simply compare very broad trends in school characteristics to trends in the return to schooling. It seems, on the basis of this comparison, that there may be an important relationship between

* University of California, Los Angeles and the Rand Corporation. This research is supported by a grant from the U.S. Office of Economic Opportunity to the National Bureau of Economic Research. schooling quality and income, or at least the possibility that such a relation exists should not be dismissed without further research.[1]

In reference to the early estimates, I think we erred by not considering the full implications of secular changes in schooling quality. The estimates are based on observations around 1960, and at that time the majority of the black adult population would have been in school in the decades of the 1920's and 1930's. During those periods, blacks attended school only about two-thirds as many days as whites. Furthermore, approximately one-third of all black students enrolled in public elementary and secondary schools in the segregated South were enrolled in the *first* grade. There were typically more than twice as many first as second graders—suggesting that retardation rates exceeded 100 percent, i.e., the average black pupil spent something more than two years in the first grade. Also, southern schools spent a little more than three times as much on white as on black pupils. In this context, it should not be surprising that schooling contributed much less to black than to white income. Given the substantial improvement in the relative quality of the schools attended by blacks in the past few decades, it should not be surprising that vis-à-vis the return to schooling, young blacks—more recent graduates—fare better in comparison to whites. And that, pure and simple, is what the data show.

II. A Reexamination

In this paper, the contributions of schooling to earnings are compared between blacks and whites for two bodies of data. The first is the 1 in 1000 sample from the 1960 Census and the second is the Survey of Economic Opportunity (*SEO*) Census income refers to earnings in 1959, and *SEO* refers to 1966 earnings. Comparison is restricted to urban males (Negro or white) who are not in the military, are not enrolled in school, and are not working without earnings. In the subsamples drawn, the Census contains 14,918 whites and 1,749 Negroes and *SEO* contains 6,379 whites and 3,442 Negroes.[2] The *SEO* data are potentially the richer source for making black-white earning comparisons because the sampling procedure insured a larger proportion of blacks. The *SEO* increased the percentage of blacks by adding to a national random sample of about 30,000 individuals, a companion sample including about 20,000 persons from "poverty" areas. It is unfortunate that stratification was based upon an income correlate, for this carries the potential of introducing biases via "creaming" of the economic successes.[3]

The point of departure for the income comparisons is the stratification of the individual observations by race and an estimate of the time of entry into the labor

[1] Lewis Solmon has recent evidence linking college traits to earnings. Also, the work of Frank Stafford and George Johnson is relevant.

[2] The Census contained observations for 56,732 males between 14 and 70 years of age who, if they reported a positive number of weeks worked, reported positive earnings. Of these, 40,065 were eliminated: 6,835 were rural; 26,902 either had "negative" work experience, were in school, or had more than 25 years experience; 169 worked without pay; and 529 were neither Negro nor white, the remainder were either in the Armed Forces, reported positive earnings for zero weeks worked, or there was missing information on working class. The *SEO* sample of males 14 to 70 years contained 28,552 persons. Of these, 18,231 were eliminated: 378 were in the armed forces; 6,000 had rural residence; 10,992 had either negative experience, were in school, or had experience in excess of 32 years; 31 worked without pay or were missing information on working class an additional 230 had race other than Negro or white; others eliminated had inconsistencies between earnings and weeks worked.

[3] As schooling increases income, it increases the probability that an individual will not be in the sample. Thus, as schooling increases, we observe increasing proportions of those who are "losers" relative to the norm, and systematically understate the increase in "expected" income associated with schooling.

force. This estimate was expressed as years of work experience.[4] The Census experience classes are 1–4, 5–12, and 13–25 years. These workers would have entered the labor force approximately between 1955–58, 1947–54, and 1934–46, respectively. Their schooling would presumably have occurred in the years prior to entry into the workforce. The *SEO* sample is conformably partitioned into experience classes of 1–3, 4–7, 8–11, 12–19, and 20–32 years. Since *SEO* refers to 1966 income, the last three classes correspond to the 1959 Census cohorts. The first two classes represent entry into the labor market between 1963–65 and 1959–62, respectively.

The estimated earnings equations are of the form:

$$(1)\quad \log Y = a_0 + a_1S + a_2 \log W + a_3ZY + a_4F + a_5SF + u$$

Observations are of individuals and variables are defined as follows:

1) *Log Y* is the natural logarithm of annual earnings when earnings are positive; it is set equal to zero when earnings are zero.

2) *S* refers to years of school completed. The coefficient estimate, $\hat{a}_1$, is thus an estimate of the proportional increase in earnings associated with an extra year of schooling (when other independent variables are held constant).

3) *Log W* is the natural logarithm of weeks worked in the year for which earnings are reported. The coefficient $\hat{a}_2$ estimates the elasticity of earnings with respect to time worked.

4) *ZY* is a dummy variable that takes the value one when earnings are zero, and is zero otherwise.[5]

5) *F* is a dummy variable that equals one if the individual is a federal employee and zero otherwise.

6) *SF* is a measure of the federal government's share of the industry in which the individual is employed. The share is equal to one for federal employees.

Thus $(\hat{a}_4+\hat{a}_5)$ estimates the percentage increase in earnings associated with direct federal employment (as opposed to working in the private nongovernmental sector), and $\hat{a}_5$ estimates the percentage increase in income associated with indirect federal employment. In a period of civil rights activism one might expect the earliest effects to appear for federal employees and in private firms in which the government has the most obvious control. These variables are included to try to identify such effects.

Regression estimates appear in Tables 6 and 7 and are summarized here.

[4] In accordance with Hanoch, I assume the following ages of entry into the labor market:

Years of School Completed	0–7	8	9–11	12	13–15	16	17+
Age at First Year Out of School	14	16	18	20	23	26	28

Experience is simply defined as current age less the estimated age at leaving school.

[5] The coefficient $\hat{a}_3$ is the negative predicted value of the average *log* of earnings for those who have no earnings. The prediction is the weighted sum of the mean levels of the other independent variables weighted by the regression coefficients. In principle, the coefficients on other independent variables are smaller, in absolute value, than they would be if the regression were restricted to those observations with positive earnings. The relationship between the coefficients reported here and those obtained in regressions restricted to positive incomes is straightforward: First, partition total variance of the ith independent variable into variance about the group (those with and without income) means and variance within each group about its mean. Let f_i represent the fraction of within-group variance attributable to those who have income. Then $\hat{a}_i = f_i\hat{b}_i$ where $\hat{a}_i$ refers to regression coefficients reported here and $\hat{b}_i$ refers to coefficients obtained from restricting the sample to persons with positive income. For the constant or intercept term, the weeks worked, and the government employment variables, a constant is assigned when earnings are zero and for these variables $f_i = 1$. Therefore the schooling coefficient is the *only* parameter estimate that is affected by introducing the zero earnings dummy.

The return to schooling is broken into two components, a direct and an indirect effect. Empirically we observe that not only do persons with more schooling receive higher wages per unit of time spent on the job but, in addition, these persons devote more time to their jobs: they work more hours per week and more weeks per year.

The direct wage effect is measured by $\hat{a}_1$. It estimates the percentage increment in annual earning associated with an extra year of schooling *holding weeks worked and the probability of zero earnings constant.* It is this component of the return to schooling which is most closely linked to productivity and therefore is most obviously affected by trends in quality of schooling. When education received in a school year is of higher quality, the coefficient is expected to be higher.[6] This coefficient (plus one) is the relative wage of a person with an extra year of schooling, and can be taken in a competitive market as an estimate of the marginal rate of substitution of a worker with given schooling for a worker with an extra year. As such, it is sensitive to factor proportions and in the aggregate may fall as average schooling levels rise.

The second component in measuring the earnings gain from schooling is the compounding of earning differentials that result from comovement between wage rates and time devoted to work. Here the indirect effect refers to percentage increments in earnings related to the increased number of weeks worked and the reduced probability of having zero earnings that are associated with increased schooling. This effect is measured as:

$$\hat{a}_2 \left.\frac{d\,log\,W}{dS}\right|_E + \hat{a}_3 \left.\frac{dZY}{dS}\right|_E \tag{2}$$

The terms

$$\left.\frac{d\,log\,W}{dS}\right|_E \quad \text{and} \quad \left.\frac{dZY}{dS}\right|_E$$

are auxiliary regression coefficients on schooling holding experience constant. Two auxiliary regressions are estimated, one in which the dependent variable is *log W* so that the coefficient is the proportional increase in weeks worked associated with an added year of schooling. In the other the dependent variable is the *ZY* dummy and the schooling coefficient is an estimate of the change in the probability of having zero earnings associated with an extra year of schooling. These coefficients are reported in Tables 6 and 7 with estimates of the earnings equation. For computing variances of estimates, these auxiliary coefficients are treated as constant.

A complete specification of factors determining the indirect return of schooling is beyond the scope of this paper, but I will note a few of the more obvious possibilities. First, if unemployment is involuntary, the auxiliary relation between time worked and schooling may refer to statistical screening of employees. Schooling reduces job search time. Insofar as this phenomenon is important, we expect a contracyclical component in the indirect return. In a period like 1959 of relatively high unemployment, the impact of involuntary unemployment is greatest for the less schooled. We also expect this auxiliary correlation between schooling and time worked to attenuate over the working career as better measures of worker quality emerge. The second alternative is that the auxiliary relation between work and schooling (the indirect effect) is simply a labor supply response to the direct or wage rate effect (see C. M. Lindsay).

[6] As an example, define education as the product, quantity times quality of schooling. In the model, $log\ W=\alpha_0+\alpha_1 E$, where W is the hourly wage and E is education. Since $E=QS$, quality times quantity of schooling, the percentage return to quantity is $\alpha_1 Q$.

TABLE 1—PROPORTIONAL INCREMENT IN INCOME ASSOCIATED WITH ONE ADDITIONAL YEAR OF SCHOOLING[a]

20–32	.110	.069	.041	.096	.049	.042

[a] Standard Errors are not reported, but were typically small relative to the coefficients. For total returns, t-ratios ranged between 5.2 and 33.0, between 14.6 and 32.0 for direct returns, and for indirect returns, between 2.3 and 11.7 for whites and 1.8 to 5.0 for blacks.

If the supply of labor is positively sloped, we then expect the direct effect, which captures the wage increment, to be positively related to the indirect effect, which embodies the resultant work response.[7]

Table 1 reports estimates of the total, direct, and indirect returns to schooling. The sum of the direct and indirect effects is not constrained to equal the total effect, because a provision for federal employment is also included. The covariances between federal employment and schooling are consistently positive, both for blacks and whites, but the contribution to the return to schooling is numerically trivial even though it occasionally is "statistically significant."

Several patterns in these coefficients reported in Table 1 are of interest. The most obvious is the attenuation in the cross-section of both direct and indirect returns as experience increases or as "vintage" decreases. In 1959, a year of fairly high unemployment, the indirect effects actually exceed the direct effects at lower levels of work experience, although the pattern quickly reverses itself as experience increases. Further, the share of the indirect in the total effect is larger for blacks than for whites. This adds support to the hypothesis of involuntary unemployment, with the heavier burden falling upon blacks and upon persons with little experience, i.e., persons for whom the years of school completed represents an important part of the information available for assessing productivity.

In the 1959 data, the evidence is that for persons with 1–4 years of experience, black earnings rise relative to white earnings as school completion levels increase. This point has not been previously noted. For persons with 5–12 years of experience, the black/white earning ratio is insensitive to schooling and for persons with 13–25 years of experience relative earnings

[7] In fact, if there is no involuntary unemployment and if schooling is competitively purchased such that there is no income or wealth effect, the ratio of the indirect to the direct effect is an estimate of the substitution component in the labor supply function. The indirect effect is the time worked response to the wage change accompanying increased schooling so that the ratio of this to the wage response to schooling gives an estimate of the rate time at work responds to wage increments.

of blacks fall as schooling increases.

The 1966 data presents patterns that are generally similar to those found for 1959. At low levels of experience, the black/white earning ratio rises with schooling, but at higher levels of experience, the opposite is true. Interestingly enough the share of the indirect in the total return to schooling is similar between blacks and whites in the relatively tight labor market that prevailed in 1966.

Because the indirect effect is likely to contain important life cycle and business cycle influences, a comparison of the effects of secular trends in the relative quality of black schooling is more safely founded in comparisons of direct effects alone.

The first panel of Table 2 presents t-statistics for black-white differences in the direct return to schooling in 1959 and 1966 within experience classes. Panel II gives t-statistics for the black and white cohorts for differences in direct returns between 1959 and 1966. These statistics simply confirm what is obvious in Table 1. For those with 1–4 years of experience in 1959 or 8–11 years in 1966 there is no significant black-white difference. As experience extends to encompass persons who entered the labor force before the mid-1950's, the difference cumulates becoming "significantly" higher for whites especially in the 13–25 and 20–32 experience classes. But, for persons entering the workforce in the 1950's the evidence is that returns are significantly greater for blacks. That is, viewed as a proportional contribution to earnings, schooling yields more to blacks than whites when comparisons are restricted to recent vintages. The earlier vintage comparisons yield the opposite conclusion.

That this effect is primarily one of vintage—not a life cycle effect in which schooling initially offers more to blacks but quickly peters out—is evidenced in the cohort comparisons. Of six comparisons, the direct returns to schooling are remarkably similar in a numeric sense, and statistically they change significantly in only one case of six as the cohorts add seven years of experience. More generally, the

twelve equations in which the six cohort comparisons are based were "stacked" into a single regression equation for which it is possible to jointly impose the constraints of cohort equality for the schooling coefficients in 1959 and 1966. The computed $F(6;24,705)$-statistic on this constraint is 1.73 with a 0.05 critical level of 2.10.

This is not to say that there are no life cycle effects associated with the return to schooling,[8] but if such effects exist they are swamped in these data by the general "tightening" of the labor market that occurred between 1959 and 1966. To summarize, the evidence is that, viewed as a proportional contribution to earnings, returns to schooling have increased for blacks relative to whites. For those entering the workforce in the 1930's and early 1940's (who were schooled over the ten to fifteen years preceding entry to the market), returns for blacks were significantly less than for whites. Yet the opposite is true for those entering the labor market in the 1960's. Furthermore, in the cohort comparison this return does not attenuate as experience increases. Since rapid attenuation occurs in each cross-section, the implication is that vintage is an important explanation. This interpretation is also presented by Leonard Weiss and Jeffrey G. Williamson in a separate analysis of the *SEO* data.[9]

This vintage effect could be interpreted as changes in labor market conditions with changing attitudes toward discrimination. Suppose that the labor market is such that a person's career profile is largely determined by conditions that exist at the time he enters the workforce, and that "taste for discrimination" has been falling over time. This would predict the improving relative position of blacks, but would not explain the obvious vintage effect for whites. As an alternative, consider the effects of quality of schooling. The evidence is that real inputs into predominantly white schools have increased through time and that black schools have improved relative to white schools. This is sufficient to explain the observations reported in Tables 1 and 2. Given this possibility, turn to evidence of schooling's quality.

III. Schools for Blacks

Until we are more knowledgeable about the technology of learning and about exactly what it is that schools produce that allow more schooled persons to earn more, comparisons of schooling quality will be superficial at best. Nonetheless, we do have fragmentary evidence that both in terms of the facilities schools offer to students and in terms of measured achievement, blacks are gaining relative to whites. This is not to say that we have achieved parity, but only that trends are in the "right" direction.

[8] In fact, at very low levels of work experience there is good reason to expect a life cycle component in the direct return as well as in the indirect return. Bear in mind that an extra year of schooling, experience constant, implies that age also increases by one year. In fact, in the estimates used here, the age of entry into the labor market rises something more than a year with an added year of schooling. At relatively young ages this maturation effect, included in the return to schooling, may be important.

[9] It is not clear that a distinction between life cycle and vintage effects is possible using a single cross-section. Weiss and Williamson observed that over the age interval, 20–49 years, and within the schooling interval, 8–12 years, the percentage increment in earnings from schooling falls as age increases. This is not true for persons who have attended college nor is it true of those who are 50 years old or over. Weiss and Williamson purport to test the impact of inferior southern schooling by using the variable for residence at age 16 that is available in *SEO*. Unfortunately, they did not allow interaction between schooling and this early residence variable, so that the marginal value of schooling is assumed independent of location. This formulation is then not a test of quality. In fact, given the evidence of trends through time presented here, I would argue that the appropriate test concerning quality of schooling involves interaction between vintage, early residence, *and* schooling. The introduction of dummy variables for early residence does not adequately specify the role of schooling's quality.

In Table 3, summary statistics are offered for segregated southern schools for selected years between 1919–20 and 1953–54. With the Supreme Court decision of 1954, the publication by the federal government of segregated school system statistics stopped. It is difficult to say how seriously these comparisons should be taken. Clearly, not all blacks attended school in the South. Less clearly, the relative quality of school offerings may have been better outside the South. Nonetheless, the data of Table 3 indicate a very strong upward trend in virtually every measure of schooling quality I could find, and it is this trend I want to stress.

The change that may have been of greatest importance, in terms of total learning in this century, has been the convergence in the length of school terms between urban and rural areas and between the South and other parts of the country. Because blacks were concentrated in the rural South prior to World War II, they may have been penalized most by the shorter school terms, and may have gained most by the general trend to equality of the term. As is indicated in the third row of Panel I, in 1919–20, blacks attended school only two-thirds as many days each year as did whites. Differences in days attended were more the result of

TABLE 3—COMPARISON OF TRENDS IN ENROLLMENT, ATTENDANCE, AND EXPENDITURES FOR SEGREGATED NEGRO PUBLIC ELEMENTARY AND SECONDARY SCHOOLS IN THE SOUTHERN UNITED STATES TO TRENDS FOR ALL SCHOOLS, 1919–54

differences in the length of the school term than in attendance rates. By 1953–54, black-white differences in days attended had virtually disappeared. The overwhelming difference between black and white schools in the 1920's and 1930's was in the composition of enrollment. In this period, typically one-third of all black elementary and secondary school pupils were enrolled in the *first* grade. Retardation rates appear to have been phenomenal in both the first years of elementary and secondary school. For example, prior to 1940 there were consistently more than twice as many black pupils enrolled in the first as in the second grade, and about one and one-half as many in the first as in the second year of high school. Since school enrollment was increasing at only 1 or 2 percent per year, the bulk of this discrepancy is retardation between grades one and two, and in high school it is a combination of retardation and "dropping out."[10]

By 1953–54, the ratio of first to second graders had fallen to 1.45 and the number in the first year of high school, relative to the second, had fallen to 1.30. Another important trend in the composition of enrollment was the rapid increase in the proportion attending secondary school. In 1919–20, only 1.6 percent of all black pupils in public schools were enrolled in high schools (in comparison to 10.2 percent of white pupils). By 1953–54 this proportion increases to 16.2 percent.

Expenditures on the black schools appear to have lagged behind the increases in attendance, enrollment, and the reductions in retardataion, but the trend bebetween 1940 and 1954 is impressive. Teacher salaries increased from a relative level of 57.5 percent of the salaries of southern white teachers to 85.0 percent in the later year. Similarly, expenditures rose from 31 percent of southern white levels in 1931–32 to 61 percent in 1953–54. Perhaps the levels of relative expenditures were a social crime at the time of the segregation decision, but the trend had been upward and had apparently accelerated after the beginning of World War II. And it is this upward trend that is an outstanding candidate for explaining the substantial trend in the value of schooling to blacks in comparison to whites. Recall that those in the experience class 13–25 years in 1959 would have last attended school between 1924 and 1945. Maybe the question of why returns were so low should have been reversed: If expenditures by school systems are the norm, then the relative value of black schooling is only slightly less than expected.

There is scattered evidence that the southern story of separate but unequal schools was partly true of the North—slightly less separate and slightly less unequal. Harold Baron offered some evidence for Chicago in 1961, 1963, and 1966. He argues that in 1961 there were significant differences in expenditures within the city's educational system which favored white students. By 1966, this expenditure difference had disappeared.

The Board of Education in New York City annually gives nationally standardized reading tests to third, sixth, and eighth grade pupils, and school average scores are available. Table 4 summarizes estimates of black-white differentials for selected years between 1957 and 1969. The technique used for measuring these differences is based upon the identification of *de facto* segregated schools, since only school averages, not individual scores, are available. Once again, the story of reading score differentials is pretty much the same as for income differences and for the segregated southern schools of an earlier period.

Viewed in absolute terms, there are very

[10] Since there were always more students enrolled in the first year of high school than in the last year of grade school, the evidence is for retardation.

TABLE 4—COMPARISON OF BLACK-WHITE READING SCORE DIFFERENTIALS BY GRADE LEVEL; *De Facto* SEGREGATED NEW YORK CITY SCHOOLS, SELECTED YEARS, 1957–69[a]

Black	3.31	5.38
White	4.37	7.60

Source: The Board of Education of New York City, unpublished data.

[a] These data are weighted averages of school reading score averages within each class. Third and sixth grade scores refer to elementary schools. The scores are normalized to allow for year-to-year variation in the time the test is administered. The criterion for selecting schools for these computations varied from year-to-year as data availability permitted.

Black Schools: The object was to select a modest number of reasonably large schools with the largest proportions of black students. The third grade data refer to from 21 to 28 schools, each having 700 or more pupils with at least 90 percent black. The sixth grade data are for the same schools, except that in 1965 and 1969 only eleven of these elementary schools had sixth grades.

White Schools: The number of elementary schools ranged between 23 and 27 with enrollment exceeding 800, at least 97 percent white.

large black-white differentials, and these differences compound as years completed increase. Whatever forces result in differences by the third grade appear to continue to operate at the sixth grade. The important evidence of Table 4 lies in the trend between 1957 and 1969. For third graders, a 1.40 years reading deficit eroded to 1.06. In twelve years, black third graders in New York City improved an average of .64 years in reading achievement This is reason for optimism. The reduction in the deficit for the sixth grade is a little more ambiguous. The deficit falls from 2.93 years to 2.22—a larger absolute improvement, but about the same fraction (25 percent) of the original deficit as for third graders. Certainly the gain for blacks from 4.88 to 5.38 is important, but the norm is 6.5, and the deficit remains large. Notice that children in the sixth grade in the spring of 1969 would have entered school no later than fall of 1963, and would therefore have missed the Headstart Programs. Also, given the rapid rise in black school completion levels, the average education levels of parents of black third graders in 1969 would have exceeded the average schooling of parents of black sixth graders so that these increments may refer more to changes in home than in school environment. For purposes of this analysis the important point is that the "knowledge" associated with given school completion is rising for blacks relative to whites. The question of why these changes occur is not relevant.

The fragments of evidence tell a consistent story. Schools for blacks may be inferior to those for whites and much improvement is still in order, but the record is undeniable. Improvement has occurred.

IV. Earnings and Returns to Schooling

Table 5 reports average earnings and the associated earning increment from a single year of schooling, estimated from the earning equation when schooling is held constant at 12 years.

From 1959 to 1966 the black/white earnings ratio increased by 0.12 and 0.13 for the two less experienced cohorts and by 0.23 in the third cohort. This suggests that much of the gain over this seven-year period may be serendipity of the business cycle, subject to erosion as labor mar-

TABLE 5—ESTIMATED AVERAGE ANNUAL EARNINGS AND THE VALUE OF AN EXTRA YEAR OF SCHOOLING BY RACE AND EXPERIENCE[a]

4–7	3880	5024	.77	550	530	1.03
8–11	4160	5968	.70	330	490	.67
12–19	4420	6800	.65	270	610	.45
20–32	4300	6690	.64	210	460	.46

[a] Average income is predicted from the regression equations of Tables 6 and 7. Where an auxiliary structure is estimated between schooling, S, and another independent variable, x, the mean level of that variable is adjusted to $S=12$, according to $\bar{x}(s-12)=\bar{x}+b(12-\bar{s})$, where b is the auxiliary regression coefficient. Mean income is estimated as the antilog of the predicted mean *log* of earnings plus one-half of the residual variance. The variance adjustment results from an assumption that the residuals are lognormal and increases the income predictions by 15 to 30 percent. The estimated return to schooling is the schooling coefficient (the direct return) times estimated mean income at 12 years of schooling.

ket conditions weaken. It seems reasonable to predict that had the 1966 observations occurred alongside the 1959 labor market, the earning ratios would decline to their 1959 levels. If so, then instead of relative earnings between .77 and .90 for those beginning work in the 1960's, the ratios would have been something like .64–.77. Although vintage effects appear to be pushing toward earnings parity, the gap remains large.

Variables for direct and indirect governmental employment were added to the regression equations to try to disentangle the effects of activities of the federal government on relative black earnings. The results are that, although these variables are statistically significant, the total effect, allowing for employment shares, is numerically small. Direct governmental employment increased average black earnings relative to the white average by 1 to 2 percent in both 1959 and 1966, and the effects of indirect governmental employment are similar. Blacks who work for the government (directly or indirectly) gain relative to whites, but the proportions so employed are small enough that the total effect remains small. Nonetheless, since the earning differential between private and governmental employment is large for blacks, there is an apparent incentive to acquire these jobs.

V. Summary

This paper is an empirical attempt to identify some of the structural components of the observed rapid rise in the relative earnings of blacks in the United States between 1959 and 1966. It is clear that much of the gain is associated with tightening labor markets: In 1959 white high school graduates in all experience classes worked 15 to 20 percent more "weeks" than blacks whereas the discrepancy fell to about 2 percent in 1966.

But, even though this cyclic component is important in accounting for the rise in relative earnings, there is also a vintage effect to be considered. In comparison to whites, blacks who have entered the workforce in recent periods fare better than earlier entrants.

Part of this gain results from a convergence of school completion levels. For example in the Census, blacks with 1–4 years of experience averaged 11.1 years of schooling as compared to a white average of 12.8. Yet for those with 13–25 years of experience, the black average was 8.8 years and 11.4 for whites. Clearly part of the gain in relative earnings of younger blacks comes from this relative increase in average school completion, but a more important part of the gain comes from the combined effect of increased schooling and an increased return to schooling. For example, based upon the direct returns to schooling (holding constant weeks worked and the probability of zero earnings) for the cohort with 13–25 years work experience in 1959, the rise in black average school completion would have resulted in an increase in earnings of 9.2 percent, and taking the increase in white schooling into account, relative earnings would have increased by only 0.2 percent. Yet based upon the direct returns realized for the cohort with 1–4 years of experience, the increase in black earnings resulting from increased average schooling would have been 18.2 percent and earnings, relative to whites, would have risen by 5.0 percent.

Clearly, the complete picture of relative black earnings cannot be obtained from a reference to quality of schooling, but examination of the data suggests that schooling quality is important. For both blacks and whites, the cross-sectional evidence is that the proportional contribution of schooling to annual earnings declines sharply as experience increases, or, since these are cross-sections, as vintage decreases. Yet in comparing six cohorts (three experience classes for blacks and whites separately) this attenuation does not occur in the seven-year interval between 1959 and 1966. The direct return to schooling is remarkably constant over this period, suggesting that the experience-vintage effect of the cross-section is really only a vintage effect: More recent entrants into the workforce enjoy higher returns to schooling than do those persons schooled in an earlier period. Further, this upward trend is stronger for blacks, such that the percentage contribution of schooling to earnings is larger than for whites in comparing persons who entered the labor force in the 1960's but is significantly lower for those who entered in 1930's and 1940's.

To get a feel for the underpinnings of this change, I turn to a comparison of black-white differences in statistics of schools. There, the data are clear: Through time the relative quality of black schooling has risen rapidly. In the segregated South there were important differences in enrollment, attendance, and expenditure patterns at the time of the 1954 desegregation decision, but these differences are dwarfed in comparison to those of the 1920's and 1930's. Since 1954, partial evidence of continuing convergence in schooling quality is offered by referring to a study of the Chicago schools that found black-white expenditure differences vanishing by 1966. For New York City schools, reading score data for *de facto* segregated schools indicate that about one-third of the discrepancies existing in 1957 had disappeared by 1969.

There are, of course, many alternative explanations for the vintage effects of rising relative black income: a downward drift in market discrimination being the simplest and most obvious. It seems reasonable to expect that whatever social, political, and judicial forces allowed convergence in offerings to black and white students also have allowed convergence in

offerings to black and white workers. The role of alternative hypothesis is confounded because most would not be exclusive of the quality phenomenon, but would be supplementary to it. It would be helpful to be able to identify the partial effects of the several forces that have been operative, but I doubt that available data are capable of such fine distinction. Certainly the data reported here are not.

In behalf of the quality of schooling hypothesis let me summarize the trends revealed here with which alternatives must contend. First, not only have relative black incomes increased but the gain has been greatest for higher school completion levels. Second the phenomena of rising returns to schooling is not only true in comparing black relative to white incomes but holds within the races as well: Young blacks fare better in comparison to young whites than do older blacks in comparison to older whites *and* schooling contains more of an income boost for young blacks and young whites than for older generations of their own races.

The Friedman-Meiselman CMC Paper: New Evidence on an Old Controversy

By William Poole and Elinda B. F. Kornblith*

In 1963 Milton Friedman and David Meiselman published a paper for the Commission on Money and Credit, in which they attempt to test the relative predictive power of Keynesian and monetary theories of business fluctuations. Their methods and conclusions were sharply disputed in papers by Donald Hester (1964a), Albert Ando and Franco Modigliani (1965a), and Michael DePrano and Thomas Mayer (1965a).[1] Our purpose is to review this controversy. Our method is the simple one of first replicating the studies over the original sample periods and then examining the postsample performance of the competing equations.

On a sociological level there can be little doubt that this controversy was, and continues to be, enormously valuable. Many economists have been stimulated to work on the questions disputed by the monetarist and Keynesian combatants, and it is probably correct to argue that two models of the *U.S.* economy—the St. Louis Federal Reserve and the FRB-MIT-PENN models—are a direct outgrowth of the controversy. What has been missing from this continuing controversy, however, is an *ex post* evaluation of the earlier empirical work. In Section I we present an evaluation of the equations offered by F-M, H, A-M, and D-M. This section also includes an evaluation of the reduced-form model estimated by Leonall Andersen and Jerry Jordan (A-J). In Section II we appraise the significance of the results.

I. Evaluation of Equations

The purpose of this section is to measure the performance of the equations offered by F-M, H, A-M, and D-M in the 1959–70 period, which is beyond the period originally used for estimation. As a check on the postsample results, we have also looked at the A-J equation. Although F-M emphasized the importance of using the longest possible historical period to test the rival theories, the subsequent papers by H, A-M, and D-M relied primarily on annual data from the 1929–58 period.[2] The data have been revised since the original studies were published, and we first reestimated all of the equations over 1929–58 period using data available in late 1971.[3] Our esti-

* Senior economist, Board of Governors of the Federal Reserve System, and graduate student, University of Rochester, respectively. Barbara McFadden provided programming assistance. We are, of course, solely responsible for the analysis and conclusions of this paper.

[1] The following abbreviations will be used in the remainder of this paper—F-M: Friedman-Meiselman; H: Hester; A-M: Ando-Modigliani; D-M: DePrano-Mayer; A-J: Andersen-Jordan.

[2] We have concentrated on equations using synchronous variables and annual data in current dollars since the original controversy centered on these equations. However, there is a brief discussion of the A-J equation which uses quarterly data.

[3] The source of national income accounts data for 1929–63 is *The National Income and Product Accounts of the United States, 1929–1965, Statistical Table*; the sources for 1964–70 are the July issues of the *Surv. Curr. Bus.* for 1968, 1969, 1970, and 1971. A few minor items not reported in these sources were obtained from the Department of Commerce. The source of money supply data for 1947–70 is "Revision of the Money Stock," *Fed. Res. Bull.*, Dec. 1970, pp. 895–98; the source of the money supply data for 1929–46 is Friedman and Schwartz, Table 1A, pp. 704–33, linked to the Federal Reserve series by an analysis of the two series over the 1947–60 period during which they overlap.

mates are very similar to those reported in the original papers.[4]

We have used a definition of M_2 that includes large certificates of deposits (*CD*) in spite of the fact that the definition in general use today excludes large *CD*'s. The reason for this choice is that neither F-M nor any of the others argued at the time of the original controversy that large *CD*'s should be excluded. At that time the argument was over the appropriate definition of the autonomous expenditures variable. Nor was there any discussion that the empirical definitions of any of the variables should be revised over time according to considerations spelled out *ex ante*. It would be impossible to perform an unbiased postsample test of the competing regression equations were we to permit changes in the definitions of the variables or in the form of the regressions. In fact, it turns out that excluding large *CD*'s from the definition of M_2 would reduce the postsample predictive performance of the M_2 equation offered by F-M by increasing the amount of underprediction.

In addition to estimates using M_2 as the definition of the money stock, we have added estimates using M_1 since the rapid growth of large *CD*'s since 1959 may have changed the significance of M_2 (defined either including or excluding large *CD*'s). The growth of *CD*'s affects the postestimation performance of the equation using M_2, but not the parameter estimates of the equation since *CD* growth occurred after the 1929–58 period of estimation. We have not examined an M_2 definition excluding large *CD*'s.

A. *Regression Results Comparing Money and Autonomous Expenditures*

By our count, twelve directly competing regressions using annual data were offered by F-M, H, A-M, and D-M to test the Keynesian and quantity theories, and we have added one more using the M_1 definition of money as a part of our evaluation of the controversy. Except for one multiple regression using the variables XA and ZA (defined below), all of the regressions use one independent variable. In every case, consumption expenditures in current dollars is the dependent variable. The definitions of the independent variables are as follows:[5]

M_1 = Currency plus demand deposits adjusted at all commercial banks

M_2 = Currency plus demand deposits adjusted plus time deposits at all commercial banks

A = Net private investment plus total government deficit on income and product account plus net foreign balance

ZA = Net private investment other than in inventories plus total government purchases plus exports

XA = Net interest paid by government minus property tax portion of indirect business taxes plus government transfers other than unemployment benefits plus subsidies less current surplus of government enterprises minus statistical discrepancy minus excess of wage accruals over disbursements

A^* = ZA plus XA

A^{**} = Net private investment other than in inventories plus federal government purchases plus exports

A^{***} = Gross private investment other than in inventories plus federal government purchases plus exports

L = Net private investment plus total government purchases plus net exports

[4] Hester did not report regression coefficients in his paper and so we have not been able to compare our estimates with his.

[5] The definitions in this list are used by the following authors: Friedman-Meiselman, M_2, A; Ando-Modigliani, ZA, XA, A^*; DePrano-Mayer, A^{**}, A^{***}; and Hester: L, L', L'', L'''.

L' = Gross private investment plus total government purchases plus exports

L'' = Gross private investment plus total government purchases plus net exports

L''' = Gross private investment other than in inventories plus total government purchases plus exports.

The postsample performance of the regressions (excluding the A-J equation which is discussed later) is analyzed in Table 1. In the table column headings, Ac refers to the actual, and P the predicted level of consumption, S is the standard deviation, and r is the correlation coefficient between actual and predicted. The mean square error of prediction is decomposed into three components, $(\overline{A}c-\overline{P})^2$, $(S_{Ac}-S_P)^2$, and $2(1-r)S_{Ac}S_P$. The first component measures the extent to which the mean square error is due to squared bias, the second is the error due to the squared difference between the actual and predicted standard deviations, and the third is the error due to the lack of correlation between the actual and predicted observations (weighted by their standard deviations). For convenience, the table also reports the root mean square error, as well as the bias $(\overline{A}c-\overline{P})$.

Using the criterion of root mean square error of prediction and the equations including the war years, the F-M entry M_2 finished sixth in a field of twelve entries, not counting M_1 which was not in the

original field. Since the A-M entries are a multiple regression on XA and ZA, and a simple regression on A^* (which is the sum of XA and ZA), the field might logically be defined to exclude the two regressions using XA and ZA separately. Also, the autonomous entry A was defined by F-M and universally branded by their critics as a poor bet even before the race was run. Excluding M_1, XA, ZA, and A from the race, M_2 finished fifth out of nine. The winner of the derby is L', one of the four autonomous variables defined by Hester.

If the performance of equations estimated excluding the war years 1942–46 is examined, the same general conclusions hold. Excluding the war years improves the performance of every equation except the one using XA. Excluding M_1, XA, ZA, and A, and using estimates based on the 1929–58 period excluding the war years, M_2 runs seventh out of nine, and L''' is now the winner.

The most obvious difficulty with the performance of these equations is their almost universal underprediction as can be seen from the last column of Table 1 which gives the bias. Several possible explanations for this bias come to mind.

Consistent with the monetarist view would seem to be an explanation going somewhat as follows. The regression of consumption on M_2 was meant to account for long-run effects. Since no effort was made to account for the dynamics of adjustment, it is not surprising that there are long strings of residuals of the same sign. If the war years are included in the period of estimation, the residual in 1958 was about \$29 billion. Beyond the period of estimation, the residuals rise to \$51 billion in 1960, and then decline to \$35 billion in 1967. In addition, it might be argued that the large residual of \$71 billion in 1970 is a consequence of the interest rate ceilings on both CD's and passbook time accounts, and that these ceilings were at least partly responsible for the residuals 1965–69 as well. Since interest ceilings were not really binding during the 1929–58 estimation period but were partially effective during much of the 1959–70 period, the M_2 of 1959–70 is simply not the same variable as the M_2 of 1929–58.

Another possible argument is that the war years distort the M_2 results because the equation was not estimated over a long enough time period. Excluding the years 1942–46 improves the performance of M_2 in the 1959–70 period both by increasing the constant term in the equation from -0.954 to 2.294, and by increasing the M_2 coefficient slightly from 1.304 to 1.325. If this process is carried even further by excluding 1942–49 from the estimation period, the constant drops slightly to 1.905 but the M_2 coefficient rises to 1.367, further improving the predictions 1959–70. These predictions, not reported in this paper, still have a substantial bias but the root mean square error is lower. These coefficient estimates may be compared to the F-M estimates (reported in their Commission on Money and Credit paper) of -1.198 and 1.351 for the constant and M_2 coefficient, respectively, using observations 1929–58, and 7.812 and 1.315, respectively, using observations 1897–1958. Using the longer time span raises the constant, but clearly not by enough to eliminate the bias in predictions 1959–70. From this examination of the coefficients it would appear that the monetarist explanation of the bias would have to rely primarily on the interest ceilings argument since acceptance of the long lags argument apparently has the unsatisfactory implication of acceptance of a model with substantial prediction errors in the same direction for at least a decade.[6]

[6] Another possible explanation is that the income elasticity of the demand for money is slightly below unity. In equations of the type estimated by F-M, the income elasticity differs from unity only by virtue of the

Many economists would no doubt argue that the underprediction using M_2 (or M_1) alone is the result of the failure to take account of the interest elasticity of the demand for money. Interest rates did, of course, rise substantially during the post-sample period. This explanation requires that the single equation approach be abandoned since at least one additional equation is required to explain the interest rate.

The Keynesian explanation of the bias would probably go as follows. First, H, A-M, and D-M all argued in their original papers that the war years should be excluded from the estimation period, and so the significant improvement in the predictions from excluding the war years should not surprise these authors. But even with the war years excluded from the estimation period, the Keynesian equations generally underpredicted 1959–70.

The explanation that immediately comes to mind for the underpredictions of the Keynesian equations is their failure to include taxes. It may be recalled that the F-M definition of autonomous expenditures, A, included the federal budget deficit whereas H, A-M, and D-M all made a special point of rejecting this aspect of the F-M definition on the grounds that tax revenues were clearly induced rather than autonomous. While H, A-M, and D-M might well have included a variable such as full employment revenues in the definitions of their autonomous variables, none of them in fact did so, and so none of them took any account of income tax rates or of the revenues produced by income taxes.[7] The underprediction of the Keynesian equations in the 1960's could be the result of the Kennedy and Johnson Administrations' tax cuts in the form of the reductions in personal and corporate income tax rates, liberalized depreciation, and the investment tax credit.

B. *Multiple Regression Results Using Money and Autonomous Expenditures*

Table 2 gives, except for the first line, the multiple regression coefficients for M_2 with each of the various definitions of autonomous expenditures excluding XA and ZA. For ease of comparison, the first line of the table gives the regression statistics for the simple regression of consumption on M_2. Comparing the multiple regressions with the simple regression, it can be seen that in every case except two the addition of an autonomous expenditures variable lowers the coefficient for M_2. The two exceptions are for A and A^{**} when the war years are included in the estimation period.

These two exceptions are the only cases in which the autonomous spending variable has a negative regression coefficient. For the variable A, this finding merely replicates the F-M finding of a negative coefficient for the 1929–58 period, a finding later confirmed by Meiselman, p. 17, for the 1961–67 period. But the regression coefficients for the other autonomous expenditures variables are not negative.

As can be seen from the last column of Table 2, the multiple regressions produce better predictions 1959–70 than the simple regression using M_2 alone for every definition of autonomous expenditures except for A, A^{**}, and A^{***} for the estimation period excluding the war years. For the multiple regressions, it is again true that the major problem is underprediction.

constant term, which in the estimates is in any event very close to zero, and so the income elasticity approaches unity as the constant term becomes of smaller relative importance with the passage of time. A logarithmic formulation, on the other hand, has a constant elasticity which might well be estimated to be less than unity. Although not directly relevant to the M_2 definition of money, it is suggestive that there is some evidence that the income elasticity of demand for M_1 is about 0.85 (see Poole (1970)).

[7] The A-J paper (discussed below) did include tests involving full employment expenditures and revenues.

TABLE 2—MULTIPLE REGRESSIONS 1929–58 AND THEIR PREDICTIVE POWER, 1959–70
(The dependent variable is consumption expenditures)
(billions of current dollars)

Autonomous Variable	Constant	M_2 Coefficient	Autonomous Variable Coefficient	R^2	Standard Error	Root Mean Square Error 1959–70
A. Estimation 1929–58						
—	−1.0	1.3	—	.946	18.8	47.4
A	−4.0	1.5	−1.0	.954	17.2	33.3
A^*	4.1	1.1	0.3	.946	18.7	40.6
A^{**}	−3.2	1.4	−0.2	.945	18.9	44.7
A^{***}	1.2	1.2	0.2	.945	18.9	47.3
L	0.0	1.3	0.1	.944	19.1	46.8
L'	5.7	0.9	0.4	.954	17.4	32.7
L''	4.2	1.0	0.4	.950	18.1	37.9
L'''	5.2	0.9	0.4	.953	17.5	34.0
B. Estimation 1929–58 excluding 1942–46						
—	2.3	1.3	—	.976	13.5	37.9
A	2.9	1.3	0.1	.975	13.8	39.1
A^*	31.7	0.3	1.2	.994	6.8	16.4
A^{**}	21.3	0.7	1.0	.984	11.2	53.7
A^{***}	22.0	0.5	1.1	.992	7.8	38.6
L	20.5	0.6	1.0	.987	9.8	30.0
L'	18.3	0.5	0.8	.994	6.5	15.0
L''	19.1	0.5	0.9	.994	7.0	17.8
L'''	19.1	0.5	0.9	.996	5.6	14.6

The dyed-in-the-wool Keynesian might interpret the multiple regression results as indicating that the inclusion of money in the analysis merely worsens the predictions since the root mean square error of prediction does not always decline when M_2 is added to the regression. We would not, however, accept this conclusion because, first, the addition of M_2 does reduce prediction errors for most definitions of autonomous expenditures and, second, even within the single equation context the multiple regression model appears to be misspecified. The difficulty is that in the formulation used by F-M the addition of an autonomous expenditures variable to the regression of consumption on money pushes the regression coefficient on money down to an improbably low value. An M_2 coefficient of 0.5, for example, implies that if the autonomous variable is held constant the ratio of consumption to money will gradually decline as the stock of money grows approaching the figure of only 0.5. That the equation is misspecified is supported by the fact that in every case the problem is one of systematic underprediction. A larger coefficient for M_2 would reduce or eliminate this problem.

C. *The Andersen-Jordan Model*

The original St. Louis Federal Reserve model was estimated by A-J on quarterly data 1952:1 through 1968:2. After reestimating this equation over the same sample period, and obtaining essentially the same coefficient estimates, we have examined the model's predictions over the thirteen quarter period 1968:3 through 1971:3. This model predicts the change in current dollar *GNP* from a distributed lag on the change in M_1 and a distributed lag on the change in high-employment government expenditures.

The entries for the postsample performance of this model corresponding to Table 1 are: root mean square error $=8.9$; mean square error $=78.4$; $(\overline{A}c-\overline{P})^2=16.8$; $(S_{Ac}-S_P)^2=1.7$; $2(1-r)S_{Ac}S_P=59.5$; $\overline{A}c-\overline{P}=-4.1$. These statistics, it should be remembered, are for the quarterly *change* in *GNP* in billions of current dollars. The root mean square error of 8.9 may be compared to the equation's standard error of estimate of 4.0.

Again there is a significant problem of bias, except that in contrast to the F-M equation the problem with the A-J equation is overprediction. Accumulating the first difference predictions to obtain level predictions, the overprediction amounts to 10.9 in 1968:4, 22.1 in 1969:4, 46.0 in 1970:4, and 53.9 in 1971:3. The A-J equation appears to be no more accurate than the F-M equation using M_2.

II. Significance of Findings

The policy implications of the results in Section I are clear. From the definitions of the autonomous expenditures variables it appears that none of the variables, including even (especially?) their government expenditure components, can be predicted very accurately a year in advance. This being the case, given a forecast of the nongovernment components of autonomous expenditures, the determination of government expenditures such that a desired level of consumption will be achieved will surely lead to substantially larger errors of prediction than indicated in the mean square error column of Table 1. On the other hand, even within the present institutional framework there can be little doubt that it is technically possible to set either M_1 or M_2 very accurately on a yearly average basis. Thus, the mean square error figure for M_2 in Table 1 is an appropriate measure of the probable accuracy of stabilization efforts using M_2 and based on the F-M formulation of the money-consumption relationship.[8] None of the relationships examined in this paper are accurate enough to be of much use in formulating discretionary policy. Nor are the relationships accurate enough to suggest that much confidence could be placed in a nondiscretionary policy rule based on one of these equations.

Table 1 lends considerable support to the argument that the war years should be excluded from the estimation period. For every independent variable tested, except for XA, the exclusion of the war years leads to an equation that predicts better during the 1959–70 period. From other regressions we have run (not reported here) there is also some evidence that the exclusion of 1947–49 as well as 1942–46 from the estimation period further improves the predictions beyond the period of estimation. Given the extent of the dislocations caused by the war, it would not be surprising if the postwar adjustments lasted several years and thereby distort estimates from regressions using those years.

Appraising these results in terms of testing rival theories, it would appear that the decision must still be rated a draw. By defining autonomous variables that produced $\bar{R}^2$'s as high as M_2 did in the sample period, H, A-M, and D-M blunted the F-M claim that . . . "The results are strikingly one-sided" (1963, p. 166). Given that during the postsample prediction period M_2 ran about in the middle of the pack, and given the disappointing performance of the A-J equation, the decision must still be rated a draw. Although some of the autonomous definitions performed better

[8] This statement, of course, assumes away possible problems of bias in the estimated equation, problems that might show up only during a period when M_2 was deliberately controlled by policy makers. During the 1959–70 period, M_2 was not a policy-determined variable. (This is not to say that M_2 was unaffected by policy but only that it was not systematically controlled by policy makers.)

than M_2, others performed worse. The fact that H, A-M, and D-M produced so many different definitions of autonomous expenditures, and that these definitions perform so differently in the projection period, clearly reinforces the F-M statement that . . . "However useful 'autonomous expenditures' may be as a theoretical construct, it is still far from having any generally accepted empirical counterpart" (1965, p. 754).

The findings support the contention that neither the simple Keynesian nor the simple quantity theory models provide an adequate understanding of business cycle fluctuations. Even supposing that the F-M equation comes back on track in the future, the equation could hardly be considered satisfactory considering the size and persistence of its errors over the 1959–70 period. The situation with respect to the autonomous expenditures equations is not really any better. With eleven different definitions of autonomous expenditures tested it is hardly surprising that several did quite well over a postsample period of twelve observations. There simply is not much empirical content in the single equation approach as employed in the studies examined here.

This discussion assumes that the appropriate method of testing a theory is to examine the accuracy of its predictions of endogenous variables given knowledge of the values of the variables specified by the theory to be exogenous.[9] Such a theory, it may be noted, may not be of much value in *ex ante* forecasting if the values of the exogenous variables cannot be predicted *ex ante*. Conversely, since it may be possible to make accurate short-run forecasts of an endogenous variable solely on the basis of knowledge of the cyclical and other properties of the time-series of the variable, short-run forecasting models may not be of much value in testing rival theories. Since the controversy being examined concerns rival theories, *ex ante* forecasting is not directly relevant.

During this controversy there has been little discussion of the appropriate testing methodology. In their CMC paper, F-M take the view that . . . "the question at issue is mainly the short-term stability of the relations being compared" (p. 174). Although this criterion seems to be in conflict with the F-M preference for using a long historical series, if short-run stability is the appropriate criterion, the 1959–70 performance of M_2 is quite good. Over the postsample period, the major problem with the M_2 equation is bias; as can be seen from the next to last column of Table 1, relatively little of the mean square error for M_2 is due to a poor correlation of M_2 with consumption.[10]

It can be argued, however, that the short-term stability of relations is not the appropriate criterion since with *U.S.* economic data almost any variable will be closely related to consumption over a given period if only the period is short enough. The levels of most, and the first differences of many, series exhibit substantial serial correlations around linear time trends, but the trends themselves differ substantially from one short period to the next. Two series correlated with each other will, therefore, have high short-run correlations. But of what value is a theory that asserts that over the next ten years the relationship between X and Y will be "close" and "stable" but that there is no way of knowing whether a 10 percent change in X will "cause" a 20 percent change in Y or a 5 percent change in Y? An adequate theory to explain Y must either involve a stable long-run relationship between X

[9] This statement should not be interpreted as claiming that accuracy of predictions is all that is relevant, but rather that no theory is acceptable if it is contravened by the facts.

[10] In the 1959–70 period the correlation between C and M_2 is .997.

and Y, or offer an explanation of why and how the relationship between X and Y shifts from one relatively short period to the next by adding additional explanatory variables to the theory. The argument that a relationship has broken down because of "structural shifts" is inherently nontestable unless the shifts themselves are specified so that their hypothesized effects can be tested on another body of data.

This argument does not deny that the period by period correlations between money and consumption (or income) are impressively high. The evidence is strong that money plays an important role in business cycle fluctuations. Yet the variability of the regression coefficient for money period by period makes clear the necessity of adding additional variables to obtain a satisfactory explanation of business cycle fluctuations.

Our findings emphasize the futility of the R^2 game. The F-M critics all came up with definitions of autonomous expenditures that produced regression R^2s rivaling or exceeding the R^2 for M_2. But beyond the period of estimation many of these relationships fall apart. Whatever one's biases in terms of the Keynesian and quantity theory approaches, these findings indicate that none of the single equation models predict the future very well. The F-M and A-J equations have large post-estimation biases in opposite directions while the H, A-M, and D-M equations present a very mixed picture. In terms of verified empirical knowledge, economists have good reason to be modest.

The key to the accumulation of empirical knowledge, as opposed to the construction of empirical hypotheses, is the replication of empirical studies on new bodies of data. Such work ought to be carried out on a routine basis in economics just as experiments in the natural sciences are replicated as a matter of course. But if there is to be systematic *ex post* review of empirical work, the original investigators must put their studies in such a form that they can be replicated and used to make predictions outside the sample period used for estimation. The F-M, H, A-M, D-M, and A-J studies are ideal in this respect. But a similar study of the simultaneous equations models of the *U.S.* economy is extremely difficult because these models are in a constant state of flux. It would be interesting, and probably sobering, to examine the 1970 predictions of a simultaneous equations model of 1960 vintage.[11]

If the F-M argument is interpreted not as a brief for a single equation approach, but as a brief for an empirically testable approach, then it would seem that the only significant fall-out so far from this controversy has been the St. Louis Federal Reserve model. The construction of large models has been extremely valuable, but it is unfortunate, in our view, that there has not been much more effort spent on small models that are subject to *ex post* testing and evaluation.[12] What this controversy has confirmed is that it is easy to meet the challenge of obtaining a high R^2 during the period of estimation, but not so easy to meet the challenge of post-estimation predictive accuracy. Our challenge is for someone to find a multi-equation model constructed a few years ago that has greater postsample predictive accuracy than the equations examined in this study.

[11] Even the within-sample performance of simultaneous equations models is not always very satisfactory. For example, the 1969 version of the FRB-MIT-PENN model went far off track in dynamic simulation over the 1956–68 period. See Poole (1971) pp. 164–66.

[12] The major complaint about large models has been that they are so complicated that it is impossible to fully understand their workings. This view has some validity but should not be overemphasized because with sufficient labor it is possible to understand these models. Much more serious, in our view, is the problem discussed in the text—that is, that these large models are not really subject to *ex post* evaluation, at least not without a tremendous expenditure of resources.

On Revaluations versus Devaluations

By EDWARD S. HOWLE*

In reforming the system of pegged exchange rates, one matter of concern is the distribution of the burden of adjustment between revaluations and devaluations. The same amount of adjustment can be accomplished with various revaluation-devaluation combinations, but changing the combination has several effects. One important effect was noted in a report by the International Monetary Fund:

> Generally, and over a period of time, a predominance of exchange rate adjustments in one direction, taking account of the size of the adjustments and the relative importance of the currencies concerned, will tend to increase their number, since it will require such adjustments to be made by countries that are originally in a balanced payments position to a greater extent than if movements in both directions were reasonably matched.[1]

This point is explored in the analysis that follows. It is shown that, of all the various revaluation-devaluation combinations that could keep all countries in payments equilibrium, there is one particular combination that will minimize the number of exchange rate adjustments, with each adjustment weighted by the size of the induced trade changes that result. It is also demonstrated that, within a pegged-rate system, the particular revaluation-devaluation combination by which equilibrium is maintained affects not only the distribution of the burden of adjustment between countries, but also the total burden of adjustment. Thus, some systems would be less costly in the aggregate than others.

The paper begins by defining the adjustment pivot point; this concept is central in the analysis. There follows a discussion of the influence of the quantity of reserves upon the pivot point or upon the revaluation-devaluation combination. Then a formula is specified for the revaluation-devaluation combination (or bias) that will minimize the weighted amount of exchange rate change required over time by all pegged-rate countries. Finally, the analysis is applied to the 1960–71 period. A rough estimate is made of the reduction in trade adjustments that might result from the optimal revaluation-devaluation combination, as opposed to adjustment only through devaluations.

I. The Adjustment Pivot Point: An Analytical Tool

The pivot point can be explained by examining a world composed of countries A through K.[2] Each country has a constant rate of inflation determined by policies aimed at internal objectives. Thus, balance-of-payments considerations do not influence rates of inflation.[3] Assume that the maintenance of payments equilibrium in the long run requires that countries A through K have the average annual *relative* rates of exchange rate change (p_i values) in Table 1, stated in percentages.

* University of North Carolina at Chapel Hill. I am indebted to Clarence H. Adams, Jr., Dennis R. Appleyard, John E. Jelacic, James C. Ingram, Donald B. Keesing, Kenneth J. Kopecky, Carlos F. J. Moore, Hiroshi Ono, Steven S. Rosefielde, an anonymous referee, and others. Research support was provided by the Business Foundation of North Carolina, Inc.

[1] See *The Role of Exchange Rates in the Adjustment of International Payments*, p. 38.

[2] The pivot point concept was introduced independently by John Williamson, p. 3, and by Howle and Carlos F. J. Moore, pp. 430–31.

[3] These assumptions will be relaxed in Section II.

Assume further that a system of pegged exchange rates exists, and the band width about each parity is zero. Each country maintains payments equilibrium by periodic discrete devaluations or revaluations relative to gold and *SDR*s. The term parity will always mean the gold and *SDR* price of the currency, and a change in that price will be called a revaluation, devaluation, or parity change.

TABLE 1—RELATIVE ANNUAL AVERAGE PERCENTAGE RATES OF EXCHANGE RATE CHANGE (p_i VALUES) REQUIRED FOR LONG-RUN MAINTENANCE OF BALANCE-OF-PAYMENTS EQUILIBRIUM

p_i	Countries
0.0	*A*
2.0	*B, C, D*
4.0	*E, F, G*
6.0	*H, I*
8.0	*J*
10.0	*K*

In this example an infinite variety of revaluation-devaluation combinations could achieve the relative rates of exchange rate change in Table 1. To illustrate, adjustment could be accomplished by *A* maintaining a constant parity; *B*, *C*, and *D* each devaluing by 10 percent once every 5 years (an average annual rate of 2 percent); *E*, *F*, and *G* each devaluing by 10 percent once every 2-1/2 years; etc. In this case we would say that the adjustment pivot point is at zero on the scale of relative exchange rate changes, for the country at zero on that scale is the pivotal country; it does not adjust and all other countries adjust around it. Alternatively, the same relative rates of exchange rate change can be maintained by *A* revaluing by 10 percent once every 5 years; *B*, *C*, and *D* maintaining a constant parity; *E*, *F*, and *G* devaluing by 10 percent once every 5 years; etc.[4] In this case the pivot point is at 2 percent on the scale of relative exchange rate changes.

Thus, when all countries are maintaining payments equilibrium over time by some unique combination of average revaluation and devaluation rates, the adjustment pivot point, p^*, will have a numerical value equal to the average rate of *re*valuation for the country with the highest such rate.[5] Increasing the overall revaluation to devaluation ratio increases p^*. Also, as indicated in Table 1, p_i will mean the average percentage rate of exchange rate change of country *i* relative to the country with the highest rate of revaluation. A country's rate of parity change is $(p_i - p^*)$. For example, if p^* is equal to 6.0, country *B* must revalue at an average rate of 4 percent.

While p^* might be set at some given level by international agreement, the level of p^* might also be controlled by regulating the quantity of international reserves, provided that 1) no country with a p_i value of less than the desired p^* prefers holding infinite reserves to revaluing, and 2) a given percentage increase in reserves does not produce an equal or larger percentage increase in price.

To see how an increase in reserves might increase the value of p^*, we begin with a quantity of reserves so small that country *A* (Table 1), in preference to revaluation, will absorb all of the existing reserves that the other countries do not choose to hold. All of the other countries, since they have higher p_i values than *A*, will be forced to devalue periodically to avoid

[4] The error involved in adding or subtracting percentages can be made insignificant by the method used in Section III below, or by specifying the percentage change for a short time period, reducing the numerical size of the percentages.

[5] Exchange rate adjustment will involve a pivot point so long as adjustment is made vis-à-vis some *numeraire*. But, with freely fluctuating rates an no official reserves, there is no pivot point. Also, as Williamson has pointed out, p. 3, if all countries adjust around one key currency of a country that never initiates a parity adjustment, p^* must be equal to the p_i value for that country; a particular revaluation-devaluation combination is implied.

losing all of their reserves to A. Country A's balance of payments will be kept in equilibrium by the devaluations of other countries, and p^* will be equal to zero. To increase p^*, reserves must be increased enough so that A will prefer revaluation to holding all of the reserves that other countries do not choose to hold. So now let every country be allocated additional reserves. Deficit countries will be able to postpone devaluation, and it seems reasonable to assume that they will do so. In fact, those countries that must continue to periodically devalue might not choose to retain any of their share of the reserve increase. Most or all of the reserve increase will eventually tend to go to A. But if the increase is large enough, A will refuse to accept such a quantity of reserves, choosing instead to revalue each time its reserve quantity exceeds some standard. This is a shift in p^*. If B, C, and D are together willing to absorb all of the excess reserves that A refuses to absorb, then the new p^* value will be 2.0. In this way an increase in the quantity of reserves might increase the value of p^*.

Further analysis of the relationship between reserves and p^* will be presented elsewhere. For the present, it is sufficient to note the concept of p^* and the possibility of changing p^* either by international agreement or by less direct means such as changing the quantity of reserves.

II. The Exchange Rate Adjustment Model

It has been noted that a predominance of exchange rate changes in one direction tends to increase their number. In other words, an extreme p^* value, whether high or low, increases the amount of necessary exchange rate adjustment by all pegged-rate countries over a given time span. What may be less clear, but will be demonstrated below, is that when parity changes are randomly distributed through time, an extreme p^* value will increase not only the amount of needed exchange rate change but also the total amount of trade change that results from all adjustments. An extreme p^* value in the pegged-rate system causes the adjustment process to be accompanied by unnecessary trade balance shifts. And because of these effects of a high or a low p^* value, there must be some p^* value that will minimize the amount of exchange rate adjustment (however weighted), or the total amount of trade-balance change, required to keep all pegged-rate countries in equilibrium over time.[6] The exchange rate adjustment model presented here will explore this.

The assumptions used in the model can be slightly less stringent than those used in the earlier numerical example. In particular, we want to admit that efforts to offset the employment and inflationary effects of a parity change may be imperfect. It is therefore specified that p_i is country i's *long-run* average position on the scale of relative exchange rate changes, but there may be short-run deviations of the country's position from p_i. However, p_i, as a long-run value, is constant, and it is independent of the location of p^* or the quantity of reserves. The independence just mentioned need not imply that the overall world rate of inflation is unaffected by a change in p^* or the quantity of reserves; p_i values will be unaffected so long as relative rates of inflation remain unchanged. Thus we assume that only relative rates of inflation are unaffected by p^* and by the quantity of reserves in existence.

It is assumed, as before, that secular tendencies to balance-of-payments im-

[6] While the pivot point is a valid concept for any exchange rate adjustment system involving a *numeraire*, the analysis of the amount of trade adjustment accompanying the adjustment process is valid only for a pegged-rate system. When exchange rate changes are gradual, they may offset trade changes that would have otherwise occurred, rather than actually causing trade adjustments.

balances are corrected only by exchange rate parity adjustments, and between adjustments exchange rates are kept exactly at parities; the band width is zero. A country with p_i greater than p^* periodically devalues, while if the reverse is true periodic revaluation is necessary.[7] The average rate of parity change for country i is equal to the value of $(p_i - p^*)$. *Except where specified otherwise*, a country is assumed to base its decision to change its parity on its own payments and reserve situation, so that the decision is independent of concurrent parity action taken by other countries.

All values are denominated in units of a specific currency; a shift in p^* cannot permanently affect the value of one currency relative to another, but it does in time affect the value of every currency relative to reserves. For a given country, the size of the trade-balance change associated with a parity change is proportional to the size of the latter; elasticities are assumed to be the same for small and large parity changes by a given country. The adjustment of trade to exchange-rate changes is instantaneous.

We begin by using a numerical example to show that the value of p^* has no effect on the amount of induced trade change if parity changes are always coordinated in a particular way, but that p^* does otherwise affect the amount of induced trade change. Consider the world of six countries in Table 2.

TABLE 2—HYPOTHETICAL DISTRIBUTION OF p_i VALUES

p_i	Countries
0.0	*A, B*
2.0	*C, D, E, F*

In one way or another, *C* through *F* must depreciate their currencies relative to *A* and *B*, or *A* and *B* must appreciate relative to *C* through *F*, at an average annual rate of 2 percent if secular equilibrium is to be maintained. Assume initially that this is accomplished by *A* and *B* revaluing *simultaneously* by 10 percent once every 5 years. Let these revaluations result in a \$4 trade-balance deterioration for *A*, the same for *B*, and a \$2 improvement each for *C* through *F*. The total induced trade change, avoiding double counting, is \$8 per 5 years.

The amount of trade change resulting from parity changes can be this low only when parity changes are coordinated so that no country depreciates (appreciates) relative to another country that will later have to depreciate (appreciate) relative to the first. Let this be defined as perfect simultaneity. When adjustments are perfectly simultaneous, and only then, is the pivot point irrelevant to the amount of trade change taking place. If countries *C* through *F* had simultaneously devalued by 10 percent once every 5 years, rather than *A* and *B* revaluing, the relative change taking place is obviously unaltered, and the amount of induced trade change would still be \$8. But if adjustments are not perfectly simultaneous, the pivot point, p^*, affects the amount of trade-balance change required to maintain equilibrium, and regardless of the value of p^* the amount of such change will be greater than it will be with perfect simultaneity.

Consider, for example, the amount of trade adjustment when p^* is equal to 2.0 and adjustments are not coordinated. Countries *A* and *B* must each revalue at the same rate as before; let us assume that each revalues by 10 percent once every 5 years. With the adjustments uncoordinated, and with the assumption of instantaneous trade adjustment to parity changes, the probability is zero that the two adjustments will overlap. When the

[7] This follows from the definitions of p_i and p^*.

first revaluation takes place, it involves not only the necessary price changes between that country and the countries with p_i values of 2.0, but also an unnecessary price change between the acting country and the other country with the same p_i value. If the countries are of similar significance in trade, about 25 percent more trade is affected by the price change, and the total change in the trade balance might be as much as 25 percent larger than that attributable to the country's action in the simultaneous adjustment case. Of course, when the second of the two revaluing countries acts, it offsets the unnecessary price change between them, causing trade changes between them that reverse the initial ones. Both of these trade changes involve costs that are the result of nonsimultaneity.[8]

But, most important, observe the effect of changing p^* to zero when adjustments are not simultaneous. In that case four countries, rather than two, must adjust by 10 percent once every 5 years; with the countries of similar significance in trade about twice as much trade change will be induced as with nonsimultaneous adjustment and a 2.0 percent pivot. Each adjustment now involves a necessary depreciation relative to only two countries, and an unnecessary depreciation relative to the other three countries with identical p_i values. It is evident that, when adjustments are not perfectly simultaneous, changing p^* will alter the total amount of trade change accompanying the adjustment process.

We have seen that, with perfect simultaneity of the adjustment process, the value of p^* will affect the number of parity changes required for all countries to maintain equilibrium, but will not affect the resulting amount of adjustment-induced trade change. But without perfect simultaneity, there will be unnecessary trade changes, and these will be affected by the value of p^*. To generalize the latter result, we shall now derive the p^* value that will minimize the amount of unnecessary trade changes that would occur over time with nonsimultaneous pegged-rate adjustments. We begin by defining S_i as the absolute value of the trade change per percentage point parity change, resulting from i's independent (not simultaneous) parity adjustment; S_i can be stated as

$$(1) \qquad S_i = f(X_i, M_i, n_{si}, n_{di}, e_{si}, e_{di})$$

where X_i and M_i are the values of country i's exports and imports, n_{si} and n_{di} are the elasticities of supply and demand for i's exports, and e_{si} and e_{di} the corresponding import elasticities. For example, if A's revaluation of 10 percent produces a \$5 trade change, S_i must be equal to \$0.50.

The term $S_i|p_i-p^*|$ is the average trade change per time period (in country i and elsewhere) induced by country i's parity changes. This is because S_i is the absolute value of that trade change per percentage point of i's parity change, and

[8] It is not necessary for two p_i values to coincide for coordination of parity changes to reduce the cost of adjustment. If two periodic devaluers, for example, have different p_i values, unnecessary depreciations of one relative to the other will be avoided if a devaluation by the country with the lower average annual rate of devaluation is always accompanied by an equal or larger percentage devaluation by the other. As long as that requirement is fulfilled, unnecessary depreciations by either of the two countries *relative* to the other will not occur even though the country with the higher average rate of devaluation may have additional devaluations that are not coincident with devaluations by the other country. In general then, given a distribution of p_i values and a p^* value, the requirement for perfect simultaneity will be fulfilled if 1) whenever a country devalues, that devaluation is accompanied by a simultaneous devaluation of at least the same percentage by every country with a p_i value that is equal to or higher than that of the first country; and 2) whenever a country revalues, that revaluation is accompanied by a simultaneous revaluation of at least the same percentages by every country with an equal or lower p_i value. If these two conditions are fulfilled, there will be no unnecessary appreciations or depreciations of one country relative to another. A more detailed explanation and example is available from the author.

$|p_i - p^*|$ is the average amount of i's parity change per time period. The total value of all absolute trade changes per time period, that result from the parity changes required to keep all pegged-rate countries in payments equilibrium, is

$$T = \sum_{1}^{n} S_i \mid p_i - p^* \mid \tag{2}$$

Countries 1 through n are all pegged-rate countries.

Let R be the sum of S_i values for all countries with p_i values of less than p^* (all periodic revaluers), N be the sum of S_i values for those countries, if any, that have p_i values exactly equal to p^*, and D be the sum of S_i values for countries with p_i more than p^*. This means that

$$\sum_{1}^{n} S_i = R + N + D \tag{3}$$

From equation (2) it can be shown that the change in T resulting from an infinitely small change in p^* is

$$\frac{\Delta T}{\Delta p^*} = R + \frac{N\Delta p^*}{\mid \Delta p^* \mid} - D \tag{4}$$

where Δp^* is infinitely small. Equation (4) is not a derivative of equation (2) because the derivative of $S_i|p_i - p^*|$ is undefined where p_i and p^* are equal.[9]

It is found from equation (4) that T is minimized when[10]

$$\mid R - D \mid \leq N \tag{5}$$

This is based upon the assumption that S_i and p_i values are unaffected by changes in p^*. Of course, R, N, and D values are affected, for a change in p^* can shift a country from one category to another. Generally, one and only one p^* value will distribute countries among the R, N, and D categories in a way that will fulfill the condition stated in equation (5), and that p^* value will coincide with some p_i value so that N is positive. The only exception appears to be when there is a p^* value that makes R and D exactly equal when N is zero. In this case there will be one and only one range of p^* values, extending from a specific p_i to an adjacent one, that will fulfill the condition, and this range of p^* values will all produce the same (minimum) T value.

We now know the p^* value that will minimize the amount of unnecessary trade changes accompanying nonsimultaneous parity changes over time. Ignoring the problem of finite increments, it is the p^* value that will divide countries between revaluers and devaluers in such a way that the sum of S_i values for periodically revaluing countries (or R) is equal to the sum of S_i values for periodically devaluing countries (or D). This minimization condition can be understood intuitively by considering the effect of raising p^* by 1.0 percent. For simplicity assume that there is no p_i value such that

[9] Differentiation can be used except where p_i and p^* are equal. Since the derivative of a sum is equal to the sum of the derivatives, each $S_i|p_i-p^*|$ term in equation (2) can be differentiated separately to obtain

$$\text{(A)} \qquad \frac{\partial S_i \mid p_i - p^* \mid}{\partial p^*} = S_i \qquad \text{where} \quad p_i < p^*$$

$$\frac{\partial S_i \mid p_i - p^* \mid}{\partial p^*} = -S_i \quad \text{where} \quad p_i > p^*$$

Where p_i and p^* are initially equal, $\Delta S_i|p_i-p^*|/\Delta p^*$ is equal to S_i when Δp^* is positive, and to $(-S_i)$ when Δp^* is negative. This can be stated as

$$\text{(B)} \qquad \frac{\Delta S_i \mid p_i - p^* \mid}{\Delta p^*} = \frac{S_i \Delta p^*}{\mid \Delta p^* \mid} \quad \text{where} \quad p_i = p^*$$

The only case not yet considered is where (p_i-p^*) has a small nonzero value and the change in p^* causes the sign of (p_i-p^*) to change. But the change in p^* can always be made small enough to eliminate this possibility; this case can be ignored at the limit. Equations (A) and (B) can therefore be summed and the R, N, and D notation substituted to obtain equation (4).

[10] For a minimum to exist, neither an increase nor a decrease in p^* can decrease T. From equation (4) an increase in p^* will not decrease T so long as $(R+N-D \geq 0)$, and a decrease in p^* will not decrease T so long as $(R-N-D \leq 0)$. Thus the value of $(R-D)$ must lie between $(-N)$ and N, as is stated in equation (5).

($p^* \leq p_i < 1.01\ p^*$). Each of the countries with p_i less than p^* must increase their annual average rate of revaluation by 1.0 percent. The trade changes throughout the world associated with their revaluations rise by R per time period, for that is the total trade change per percentage point of their parity change. Similarly, the trade changes induced by parity changes of those above the pivot decline by D. Thus, the total adjustment-induced absolute trade change falls with a rise in p^* if R is less than D, is at a minimum if the two values are equal, and rises if R exceeds D. This confirms the equation (5) result.

Note what equation (5) means for the special case in which all countries have identical elasticities and average trade balances of zero over time. The ratio of S_i to (X_i+M_i) will be identical for every country, and the optimal pivot will be the one that causes countries to be divided between the revaluers and devaluers so that the total trade of periodic revaluers is equal to the total trade of periodic devaluers.[11] That will probably be approximately true even if these conditions are not met. *Thus, given the lack of accurate elasticity estimates, it would make sense for countries of the world to agree upon a system of exchange rate change in which countries below the pivot have roughly the same value of imports and exports as do those above.*

Finally, two points should be noted. It has been said that equation (5) states the condition for minimizing the amount of trade change accompanying the adjustment process. But, it is equally correct to say that equation (5) states the condition for minimizing the weighted number of parity changes, where the weighting is the amount of trade change that results from each parity change. The two criteria are definitionally identical. Also, note from equation (5) that it is the division of countries between those above the pivot and those below that matters, not how far above or below countries are. The optimal value of p^* will not be affected by a doubling of the rate of inflation, and a corresponding increase in p_i, of a country whose p_i value is already above the optimal p^* value.

This completes the theoretical analysis. We have shown that, if the adjustment process is perfectly simultaneous, the value of p^* will affect the number of parity changes required for all countries to maintain equilibrium, but it will not affect the total amount of trade change that results. Regardless of the pivot point there will be no unnecessary trade adjustments in this case. But without simultaneity, the adjustment process will involve unnecessary trade adjustments; a country will depreciate (appreciate) relative to other countries that will later find it necessary to depreciate (appreciate) relative to the first. There is a p^* value that will minimize (but not eliminate) the aggregate amount of unnecessary trade change that results from nonsimultaneity. That p^* value is the one that will fulfill the equation (5) condition, subject, of course, to the assumptions stated.

III. An Empirical Illustration

The analysis will now be applied to p_i values for the period December 31, 1960 through December 31, 1971. This will illustrate the use of the model and give a rough indication of how the amount of trade adjustment varies in relative magnitude with changes in p^*.

At the time of this writing exchange rate data for the end of 1971 was obtainable for 99 countries from an International Monetary Fund press release. We added Switzerland and the United States, giving

[11] Williamson, p. 14, suggests incorrectly that parity adjustment will be minimized if all countries adjust around the one with the modal rate of inflation.

TABLE 3—SELECTED TRADE-BALANCE CHANGE COMPUTATIONS[a]

			$S_i\|p^*-p_i\|$ values where p^* equals[b]				
(1) Country	(2) p_i	(3) S_i	(4) 0.00	(5) 18.36	(6) 26.62	(7) 30.20	(8) 69.27

(8) India	69.27	6.033	418	307	257	236	0
(9) 86 country total			111,312	55,805	53,368	61,278	223,971

[a] The p_i and p^* values are stated as percentages; all other values are in dollars divided by 10^7.
[b] The p^* values listed correspond to the following pivots: 0.00, Germany; 18.36, gold and *SDR*s; 26.62, United States; 30.20, France; 69.27, India.

us 101 countries that accounted for most of the trade outside of the Soviet area. Eight countries of this group, including Canada, were excluded because of flexible rates; the analysis does not apply to flexible-rate countries. Multiple-rate countries in general were included as long as there was one principal trade rate; only the Philippines and Viet-Nam were excluded because of multiple rates. Five very small countries were excluded because of nonexistent or doubtful data. This left a group of 86 countries in the study.[12] The 8 countries in Table 3 are representative and will illustrate the calculation methods used.

It will be recalled that p_i is the average percentage change in i's exchange rate per time period relative to the exchange rate of the country that revalues at the fastest average rate. Using the entire 11 years as the time period, we have computed each p_i value (Table 3, col. 2), as

$$p_i = \frac{\log (c_i/c_1)}{\log 1.01} \tag{6}$$

The term c_i is the number of units of i's currency per dollar at the end of 1971 over the number of units per dollar at the end of 1960.[13] And c_1 is the c_i value for Germany, the country with the greatest rate of revaluation; by definition p_1 is zero. Equation (6) produces the same result that would obtain if p_i values were first computed as ordinary percentage changes for a very short time period, then multiplied by the ratio of 11 years to that time period; the effect of compounding is removed. This has the advantage that it eliminates the error that would otherwise

[12] In order of p_i values: Germany, Netherlands, Japan, Switzerland, Austria, Belgium, Algeria, Australia, Iraq, Kuwait, Libyan Arab Republic, Malaysia, Morocco, Nigeria, Saudi Arabia, Singapore, Somalia, Ethiopia, Norway, Sweden, Italy, Portugal, Surinam, Netherlands Antilles, Hong Kong, Greece, Haiti, Honduras, Iran, Jordan, Kenya, Liberia, Mexico, Nicaragua, Pakistan, Paraguay, Panama, Sudan, Dominican Republic, El Salvador, Tanzania, Thailand, Uganda, Zambia, China, United States, Denmark, Ivory Coast, Malagasay Republic, Mauritania, Niger, Senegal, Togo, Upper Volta, Dahomey, France, Malta, South Africa, Syrian Arab Republic, Sierra Lione, Barbados, Cyprus, Gambia, Jamaica, Malawi, Spain, Ireland, United Kingdom, Burma, New Zealand, Tunesia, Guyana, Costa Rica, United Arab Republic, Finland, Venezuela, Nepal, Peru, India, Turkey, Ecuador, Ghana, Rwanda, Iceland, Israel, Zaire.

[13] For sources of data used in this section of the paper, see the International Monetary Fund, New York Times, and United Nations references.

be involved in comparing large and small percentages, and in adding or subtracting one percentage from another (i.e., p^* from p_i). Also, it prevents any bias that might result from using the entire 11 years as the time period. Calculating percentages by a simple mid-range base formula produced virtually identical results, however.

Next, S_i values (Table 3, col. 3) were computed for each country, the absolute change in the trade balance per percentage-point exchange rate change. This required export values, import values, and the usual elasticities. Mid-period (1966) export and import values were used, stated in dollars, in order to eliminate the problem of deflation. Export and import values were reduced to exclude intra-bloc trade for all countries changing rates along with sterling.

Reliable elasticity values, of course, are not available for the 86 countries. But our purpose is to obtain an index of relative amount of trade adjustment corresponding to different pivots, not an estimate of absolute amounts. This means that absolute elasticity values are not very important, but relative values can matter.[14] Moreover, it would do little harm to apply the same arbitrary elasticity values to all countries as long as elasticities were not correlated with p_i values. But no industrial countries are at the extreme upper end of the p_i scale, and no less developed countries are at the extreme bottom of the p_i scale. It does not seem likely that elasticities and p_i values are unrelated. To determine how much the possible relationship between elasticities and p_i values would affect our result, we made two sets of calculations. One used the same elasticities for all countries, and the other used the assumption that export and import values were twice as responsive to exchange rate changes by the 13 industrial countries in the study as by the remaining countries. Both results will be presented. The computation of S_i values in Table 3, column 3, uses the assumption that, for every country, the absolute value of the percentage change in exports per percentage-point parity change is 2.0, and the corresponding import value is 1.0. For example, Germany, with exports of \$20,145 million, and imports of \$18,036 million, had an S_i value of 0.02 times the former, plus 0.01 times the latter, or \$58.326x10[7].

Finally, columns 4 through 8 show how the adjustment-induced trade-balance change ($S_i|p^*-p_i|$) is computed for each country corresponding to various pivots. For example, the row 2, column 6 entry shows the trade-balance change that would be induced by Japanese revaluation if p^* corresponded to the *U.S.* p_i value of 26.62; that is, if Japan and all other countries adjusted to a constant *U.S.* parity. With p^* equal to 26.62 and Japan's p_i value equal to 10.95, the relative adjustment that actually took place would have required Japanese revaluation of 26.62 minus 10.95, or 15.67 percent. Multiplying this $|p^*-p_i|$ value by the Japanese S_i value of \$29.064x10[7] gives us an induced trade balance change of \$455x10[7].

The total trade adjustment for various p^* values is listed at the bottom of the table. With the elasticity assumptions used in this example, the adjustment minimizing p^* value is 26.62, which is the same as the *U.S.* p_i value. The amount of trade adjustment is lower for the 26.62 p^* value (col. 6) than for any other p^* value, not just those listed in the table. The relative exchange rate changes that took place, if they had occurred at random times within a pegged-rate system, would have involved the least trade adjustment

[14] Doubling the assumed responsiveness of trade to parity changes will double the calculated trade adjustment corresponding to each pivot, hence it will not alter the optimal p^* or the ratio of trade adjustments for one p^* relative to those for another.

TABLE 4—EFFECTS OF ALTERNATIVE ASSUMPTIONS

Assumptions	Optimal p^*	Relative amounts of adjustment if p^* is[a] 0	18.36	26.62	30.20	69.27
(1) Same as Table 1	26.62	2.086	1.046	1.000	1.148	4.197
(2) Cost based on exports only	26.62	2.062	1.038	1.000	1.157	4.228
(3) Cost based on imports only	26.62	2.131	1.061	1.000	1.132	4.136
(4) Less developed/developed elasticity weights 1:2	21.37	2.049	1.022	1.003	1.174	4.565

[a] The p^* percentages correspond to the following pivots: 0.00 Germany; 18.36, gold and *SDR*s; 26.62, United States; 30.20, France; 69.27, India. The figures given for relative amounts of adjustment are the amounts of adjustment for the given p^* values divided by the amount of adjustment for the optimal p^*.

if the United States had not adjusted and other countries had adjusted around the dollar pivot. The amount of trade adjustment would have been more than twice that if the same relative changes had ininvolved no revaluations (col. 4).

Table 4 summarizes the way in which the conclusions are affected by altering the assumptions. In rows 2 and 3 we have repeated the calculations, first on the assumption that only export revenues change, then only import revenues. Both results are nearly identical to those obtained earlier (row 1), showing that it is not important what ratio of export to import elasticities is used. In row 4 we assumed that trade was only half as responsive to parity changes in nonindustrial countries as in the 13 industrial countries in our study. Since the industrial countries tend to lie at the low end of the p_i scale, this change in assumptions lowers the optimal p^* value from 26.62 to 21.37. But the value is still above the 18.32 p_i value for gold and *SDR*s. Note that this change in the pivot is not of much importance, the use of the 26.62 pivot increases adjustment only three-tenths of 1 percent above its minimum.

In summary, the relative exchange rate changes that occurred during 1961 through 1971, if they had taken place independently within a pegged-rate system, would have caused about twice as much trade change with no revaluations as with the optimal pivot. But the precise location of the optimal pivot is not especially critical, either the gold-*SDR* pivot (18.32) or the dollar pivot (26.62) generally gives nearly optimal results.

IV. Summary and Implications

We have considered how the operation of the pegged-rate system is affected by the location of the pivot point. The pivot point affects the number of exchange rate changes, and, unless adjustment is perfectly simultaneous, it also affects the total amount of absolute trade-balance change, and the cost of such change, resulting from parity changes. The total amount of absolute trade-balance change was selected as the objective criteria to be minimized.

It was shown that, with the assumptions stated, the amount of induced trade change is minimized when the pivot is located so that the sum of S_i values for countries that tend to revalue is equal to the sum for countries that tend to devalue. If elasticities and average trade balances are unrelated to p_i values, this means that the optimal pivot is simply the one that makes the total trade of countries that tend to revalue equal to the total trade of countries that tend to devalue.

The empirical computations suggest that the total of absolute trade-balance

changes induced by parity adjustments might be half as great with the optimal pivot as with no revaluations. Even revaluation by a few countries at the low end of the p_i scale helps a great deal. One of the limitations of the numerical estimates, however, is that we have no way of knowing how changes in the pivot point would affect the formation of currency blocs that change their rates together.

It is perhaps of some historical interest that, with most assumptions tried, the dollar pivot would have resulted in minimum, or nearly minimum, trade adjustment during the 1961 through 1971 period. If other countries had been willing to adjust around the dollar pivot the amount of adjustment within a nonsimultaneous pegged-rate system would have been about minimum. (The adjustment that finally took place in 1971 was not within the pegged-rate system or at least had some degree of simultaneity, so the present analysis does not compare that amount of trade adjustment with the minimum pegged-rate trade adjustment.) Needless to say, countries with low p_i values cannot be expected to welcome efforts to raise the pivot point. But a few revaluations did occur before the 1971 disruption of the system, and indications are that even those few considerably reduced the amount of trade adjustment during the period, or, more likely, postponed the disruption of the system.

One last point. Some people may object to raising the pivot point on the assumption that a low pivot discourages inflation. The basis for this assumption is questionable; political pressure not to devalue may be stronger when devaluations are infrequent and unfamiliar, so that if Germany and the Netherlands had not revalued in the 1960's, devaluations might have become so commonplace as to reduce their political unpopularity. But in any case, it seems unlikely that the inflation argument would eclipse the argument for reducing trade adjustments. If the inflation argument is held to have merit, the costs of inflation and trade adjustment would have to be weighted against each other. The result would presumably be a pivot somewhat above the one that would minimize inflation, and somewhat below the one that would minimize trade adjustment.

Human Capital: The Choice Between Investment and Income

By William J. Haley*

The process of investing in and accumulating human capital has been intensively studied in recent years. The fruit borne of this research can most clearly be seen in the way labor input is dealt with in nearly all empirical research now appearing in economic journals. Labor input is no longer measured as man-hours per unit of time, but an adjustment is made for the *quality* of labor input. In other words, the adjustment considers the human capital embodied in input, tending to make labor heterogeneous rather than homoegneous. The empirical benefits of dropping the assumption of homogeneous labor input is not without the substantial cost of making the theory more difficult.[1]

The literature in human capital has evolved along two essentially parallel patterns. The first, exemplified by Gary Becker, looks at individual investment and attempts to estimate the internal rate of return to that investment by equating properly discounted costs and returns. Although in theory the investments include a variety of activities which increase the individual's income stream in subsequent periods, most of the empirical work concerns estimating the rates of return to education. These studies have estimated rates of return to training individuals ranging from illiterates to candidates for Ph.D. and M.D. degrees; and one conclusion cannot be avoided—there is an economic explanation for the shape of life cycle earnings streams.

A second path along which the literature in human capital has evolved is exemplified by Yoram Ben-Porath (1967). The producer of human capital has a choice between producing additions to his stock or renting his stock in the labor market or both. He is assumed to make this choice in the process of maximizing his discounted future earning stream. In this literature, the empirical work has been rather meager, but not without reason. The principle observable phenomenon on which one must base verification of the theory is the observed income stream. The problem is then to deduce from the theory a theoretical income stream which can be compared to the observed. In general, this cannot be done. To produce an income stream from theory has been an intractable mathematical problem.

In what follows I will attempt to show the commonality between these two approaches to human capital, and in the process give one possible approach which avoids the mathematical problem referred to above. Two indirect tests are given of the model.

I. The Tie to Previous Work

One of the most important tenets of all human capital literature is that the

* Most of this work was carried out at North Carolina State University and was partially supported by National Science Foundation Grant No. GS2391. I would like to express my gratitude for helpful comments to T. Dudley Wallace, Mary Jean Bowman, Robert Fearn, Loren Ihnen, Thomas Johnson, and participants of the Econometrics and Human Resources Workshops at North Carolina State University. They, of course, are not responsible for any errors which remain. This is Michigan Agricultural Experiment Station journal article no. 5854.

[1] For example, if both capital and labor are heterogeneous the problem of aggregation, difficult to begin with, becomes even more difficult. See George Akerlof and Robert Solow.

cost of investing in oneself is measured by the earnings which are foregone during the investment period. The cost of a particular investment can be thought of as the difference between what could be earned if the investment did not take place and the actual earnings during the investment period. In particular, if we consider an individual who has made no previous investments in human capital, the cost of investment in period 1 (C_1) will be the earnings he could have made with his raw labor (X) less what he actually made in income during the period (Y_1). Thus, $C_1 = X - Y_1$. In the next period, if he continues to invest, the cost (C_2) will be what he could have earned with his raw labor (X) plus the return to the previous period's investment (r_1C_1) less his actual earnings (Y_2). Continuing with this line of reasoning, the cost of investment in period j is (see Becker, p. 65),

$$C_j = X + \sum_{i=1}^{j-1} r_i C_i - Y_j \tag{1}$$

Notice that if Y_j were combined with C_j on the left side, the sum $Y_j + C_j$ would represent the potential earning capacity of the individual. If Y_j were put on the left side and C_j on the right, equation (1) would represent earnings in period j. The sequence of values $\{Y_j\}$ for $j = 0, 1, \ldots, N$ would trace the earnings profile of a person of age N.

Becker and Barry Chiswick (1966) and Chiswick (1967) modify the model of equation (1) by defining cost in period j as a proportion of earning capacity. That is,

$$C_j = k_j Y_j^*$$

where

C_j = investment cost in period j
$Y_j^* = Y_j + C_i$ = potential earning capacity in period j
k_j = the proportion of earning capacity invested in period j

Making the substitution for C_j, equation (1) becomes,

$$Y_j^* = X + \sum_{i=1}^{j-1} r_i k_i Y_i^* \tag{2}$$

Now the choice variable is k_i. The X and r_i are exogenous to the individual, implying the time path of Y_j^* is determined by the choice of k_i made in each period. Once the path of Y_j^* is determined, the path of actual earnings can be deduced from the relation,

$$Y_j = (1 - k_j) Y_j^* \tag{3}$$

since actual earnings will be that percentage of earning capacity which is not invested. Equation (3) points out the fact that observed or disposable earnings is the proportion of earning capacity not being used for investment in period j. Clearly, the proportion of earning capacity devoted to investment is the choice variable from the individual's point of view and, therefore theoretical attention should be directed toward the determination of k_j over the life cycle.

Becker and Chiswick did not attempt to solve the theoretical question of how k_j is determined. With the help of an approximation[2] the closed form solution of equation (2) is found as

$$Y_j^* \simeq X e^{\sum_{j=1}^{j-1} r_i k_i} \tag{4}$$

[2] Chiswick shows that equation (2) can be written as

$$Y_j^* = X \prod_{i=1}^{j-1} [1 + k_i r_i]$$

Taking the logarithm of both sides,

$$\log Y_j^* = \log X + \sum_{i=1}^{j-1} \log [1 + k_i r_i]$$

Now noting that

$$\log [1 + k_i r_i] \simeq k_i r_i$$

is true for small $k_i r_i$, equation (4) follows.

where all terms are as previously defined. They assume the sequence $\{k_i\}$ to be positive during formal education and zero afterward. Figure 1 shows the shape of the sequence $\{k_i\}$ assumed by Becker and Chiswick. For any values of X and r_i, the time path of Y_j^* becomes constant after age S_3 and continues that way until the end of the earning life cycle. Therefore, their rather poor empirical results were not due to a bad model but rather the misspecification of the shape of the sequence $\{k_i\}$.

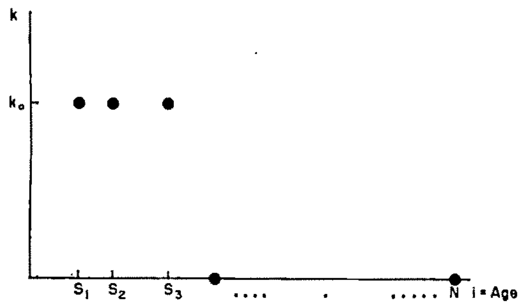

FIGURE 1. THE SEQUENCE $\{k_i\}$

Ben-Porath (1967) developed a model in which the determination of a continuous counterpart to the sequence $\{k_i\}$ could be studied. Although a closed form expression for this continuous counterpart, say $k(t)$, could not be derived, some of the characteristics of the function became apparent. Armed with this information, Thomas Johnson recognized the continuous formulation of equation (2) as a solvable integral equation whose solution was exactly equal to the continuous formulation of equation (4).[3] As with Becker and Chiswick, Johnson had a functional representation of earning capacity in terms of the proportion of earning capacity foregone as

[3] This simplified picture of Johnson's work is presented in order to show how the literature developed. Johnson solved his equation in completely general form with the rate of return, proportion of earnings foregone, and the rate of depreciation all having a time argument and an argument which included the personal characteristics of the investor.

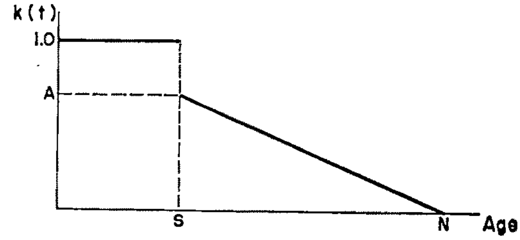

FIGURE 2. THE FUNCTION $k(t)$

well as the rate of return and rate of depreciation.[4] Using the results of Ben-Porath (1967) referred to above, Johnson assumed the function $k(t)$ had the relatively simple shape shown in Figure 2. Using this functional form for $k(t)$, Johnson's disposable earnings function had the requisite shape to articulate with observed age-earning profiles. Johnson's non-linear estimation procedure yielded estimates that seemed to make sense and his equation "fit" the data very well indeed. Certainly his procedure was a substantial improvement over Becker and Chiswick's method.

Notice that the function depicted in Figure 2 says that during formal education (ages less than S) the individual will forego his entire earning capacity in order to invest in human capital. Immediately following his formal schooling he will forego something less than 100 percent of his earning capacity for investment and, as time passes, this proportion will become smaller monotonically until, at the end of the earning cycle, his earning capacity and disposable earnings will be equal. These questions might be asked then: If an individual chooses between investment and earnings according to some objective within a choice theoretic framework, will $k(t)$ look like the one shown in Figure 2? Will it decline at a constant rate after age S? At age S, is the function $k(t)$ discontinuous—that is, does the individual evaluate human capital additions at a lesser

[4] The rate of depreciation has not been dealt with here for reasons of simplicity.

value after S than before as would seem to be implied by the discontinuity in $k(\mathrm{t})$ as shown in Figure 2? This, of course, is the neutrality hypothesis discussed in Ben-Porath (1970).

In what follows, a model which can give a theoretical answer to these questions will be formulated. In addition, a closed parametric form solution of the age-earnings profile implied by the model will be given. The economic implications of the model will be discussed as well as the results of empirical tests.

II. A Model of Optimal Human Capital Accumulation

The model proposed here will attempt to solve the problem of determining an individual's optimal stock of human capital at any given time in the life cycle, and how it should be maintained over time. It will be assumed that the problem will be solved by maximizing a particular objective function. From such a model, functions such as the path of human capital accumulation, the proportion of earning capacity foregone, and the earnings path over the life cycle can be derived in parametric form (provided the differential equations can be solved).[5]

Consider an individual or the typical individual of a group with an earning capacity of

$$Y^*(\mathrm{t}) = RE(\mathrm{t}) \tag{5}$$

where

$Y^*(\mathrm{t})$ = the individual's earning capacity at t

R = the constant rental rate per unit time on the stock of human capital

$E(\mathrm{t})$ = the total stock of human capital possessed by the individual age t

[5] For other efforts along these lines see Ben-Porath (1967), J. Ross Millar, H. Oniki, Sherwin Rosen, Eytan Sheshinski, and Yoram Weiss (1971b).

At any time t, he has the choice of renting all or any portion of his human capital stock in the labor market.

It will be assumed here that the only alternative use for his human capital is producing more human capital according to:

$$q[K(\mathrm{t})] = \beta K(\mathrm{t})^b \tag{6}$$

where

$q[K(\mathrm{t})]$ = the output of new human capital produced in period t

$K(\mathrm{t})$ = the portion of the existing stock of human capital used as input to produce more human capital in period t

β = the measure of the individual's ability to produce human capital, assumed constant over his life cycle

b = the scale parameter in the production function and is contained in the *open* unit interval

Assume, also, that capital markets are perfect. The individual's disposable earnings in any period will be the difference between his earning capacity and the cost of input used in the production of new human capital during that period. Disposable earnings, $Y(\mathrm{t})$, will be

$$Y(\mathrm{t}) = Y^*(\mathrm{t}) - RK(\mathrm{t}) \tag{7}$$

It will be assumed that the stock of human capital deteriorates at a constant and exogeneously given rate δ. The human capital stock will grow at a rate governed by

$$\dot{E}(\mathrm{t}) = q[K(\mathrm{t})] - \delta E(\mathrm{t}) \tag{8}$$

The choice facing this individual is quite clear. Since it is assumed he has no physical assets, his income-earning capacity is directly related to the size of his stock of human capital, which can grow only if he is willing to postpone part or all of his current earnings as the cost of growth. If it is assumed the individual has perfect

knowledge and there is no risk associated with his potential investment, then he will undertake the investment only when the discounted present value of the additional earning capacity attributable to the investment exceeds the value of earnings postponed during the investment period. Extending this logic, the individual's objective would be to maximize J the present value of his disposable earnings over the life cycle;

$$J = \int_0^N e^{-rt} Y(t)dt \tag{9}$$

where

N = the end of the earning life cycle
r = the rate at which the individual discounts future earnings
$Y(t)$ = disposable earnings or the difference between earning capacity and investment costs at time t

The evolution of disposable earnings over the life cycle is governed by the differential equation (8). The general form of the optimization problem is to maximize equation (9) subject to equation (8) and all the boundary equations. An explicit representation of the boundary conditions are

$$\begin{aligned} K(t) &\geq 0 \\ E(t) &> 0 \\ E(t) - K(t) &\geq 0 \end{aligned} \tag{10}$$

Application of Pontryagin's Maximum Principle after incorporating constraints (10) and the initial stock of human capital, E_0, assures the necessary conditions for a unique maximum to equation (9) with transversality conditions,

$$\lambda(N) \geq 0 \tag{11}$$

$$\lambda(N)E(N) = 0 \tag{12}$$

The interpretation of $\lambda(t)$ is that it represents the discounted marginal value of an additional unit of human capital at time t and, therefore, is interpreted as the individual's "demand price" for human capital.[6] It seems reasonable that at the end of one's earning lifetime, the marginal value of an additional unit of human capital for the purposes of generating income will be zero.[7] This means equation (11) becomes an equality.

Solving the differential equations which represent necessary conditions, the solution turns out to have two stages. The reasons for this will become clear as the discussion proceeds. In the technical jargon of control theory, the constraints force a boundary solution in the first stage whereas in the second stage the constraints do not affect the maximum thus allowing an interior solution. Both stages will be discussed beginning with the second stage.

In the second stage of the investment life cycle, the individual is producing less human capital than he is physically capable of producing (i.e., $K(t) < E(t)$). This means that the marginal cost of producing an additional unit of human capital exceeds the discounted value of additional income generated over the life cycle by that unit of human capital. Solving for $\lambda(t)$, this discounted marginal value of human capital in the second stage is,

$$\lambda(t) = \left(\frac{R}{r+\delta}\right)\left[e^{-rt} - e^{-(r+\delta)N+\delta t}\right] \tag{13}$$
$$t^* \leq t \leq N$$

where t* represents the beginning of stage two. The marginal value of human capital to the individual is independent of the quantity produced as was shown by Ben-

[6] See Kenneth Arrow. The term demand price was first used by Ben-Porath (1967).

[7] It can, no doubt, be effectively argued that certain activities which generate human capital in year N have some value. The values they have, however, satisfy utility through leisure or some other nonpecuniary argument in the utility function and not through the marginal increase in the income stream, provided year N is the last year in which the individual can earn income.

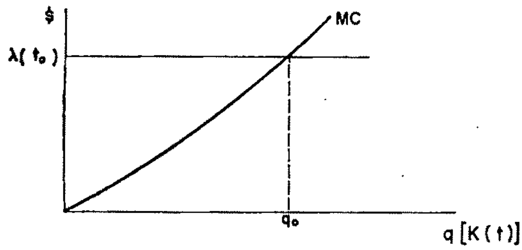

FIGURE 3. EQUILIBRIUM PRODUCTION OF HUMAN CAPITAL

Porath (1967). The quantity of human capital produced will be determined by the intersection of equation (13) with the marginal cost schedule shown in Figure 3. Over the life cycle, the marginal value of additional human capital decreases until age N, the end of the earning life cycle, when it is zero by assumption. Effectively, $\lambda(t)$ slides down the stationary marginal cost curve over the earning life of the individual.

The shape of the optimal path for $K(t)$ must now be determined given that production of human capital is determined by its marginal value. The optimal path of the human capital input to production over the second stage of this earning life cycle is:

$$(14)\quad K(t)=\left[\frac{b\beta}{r+\delta}\right]^{1/1-b}\left[1-e^{(r+\delta)(t-N)}\right]^{1/1-b}$$
$$t^*\leq t\leq N$$

where b and β are as previously defined in equation (6). A priori, it would be expected that if the marginal value of an additional unit of human capital is zero (see equation (12)), none would be produced. Equation (14) makes this expectation explicit since $K(N)=0$. The surprising fact about equation (14) is that after the individual stops specializing in the production of human capital (i.e., after stage one), the amount of capital used in the production of more human capital declines *strictly* monotonically.

The principal cause of the shape of $K(t)$ is the declining marginal value of an additional unit of human capital as shown by equation (13). Note, however, that production of human capital continues, albeit at a diminishing rate, until the end of the earning life cycle. If the life cycle were infinite, $K(t)$ becomes independent of t.

It is now possible to observe the optimal human capital accumulation path. In order to display this equation a convenient simplifying assumption of $b=1/2$ is made.[8] With this assumption the optimal path of human capital accumulation during stage two is

$$(15)\quad E(t) = Be^{-\delta t}+\frac{\beta^2}{2\delta(r+\delta)}\left[1-\frac{\delta}{r+2\delta}e^{(r+\delta)(t-N)}\right]$$
$$t^*\leq t\leq N$$

where

$$B=\left[\frac{\beta}{\delta}+\left(E_0^{1/2}-\frac{\beta}{\delta}\right)e^{-\delta t^*/2}\right]^2 e^{\delta t^*}-\frac{\beta^2}{2\delta(r+\delta)}\left[1-\frac{\delta}{r+2\delta}e^{(r+\delta)(t^*-N)}\right]e^{\delta t^*}$$

Multiplying equation (15) by the constant rate of return, R, the optimal path of earning capacity, $Y^*(t)$, is determined. Substituting equation (5) into equation (7), disposable earnings over the life cycle is

$$(16)\qquad Y(t) = RE(t) - RK(t)$$

which, after using equations (14) and (15), is determined in parametric form.

[8] The equation for optimal human capital accumulation can be solved for any real number b contained in the unit interval. For all such b when $b/(1-b)$ is an integer, the solution for $E(t)$ is a finite series as in the case given above for $b=1/2$. In the case where $b/(1-b)$ is not an integer, the solution for $E(t)$ is an infinite series. As long as b is contained in the unit interval the convexity of $E(t)$ remains unchanged as b varies. Therefore, using $b=1/2$ only makes the problem easier without making the results discussed below in any way less general. However, for certain kinds of empirical work, it is important that b be allowed to vary.

Equation (16) can be rewritten as

$$Y(t) = [1 - k(t)]RE(t) \tag{17}$$

where $k(t) = K(t)/E(t)$ is the proportion of earning capacity foregone to make current investments in human capital.

This is precisely the function which appeared in Becker and Chiswick, Johnson, and Ben-Porath (1967) as discussed in Section I. Notice that without a specific maximizing process such as equation (9), any function (or sequence in the discrete case) bounded above by one and below by zero over the life cycle, is admissible. Once the assumption is made that the individual invests in himself for the exclusive purpose of increasing his income, $k(t)$ becomes tied to zero at the end of the earning life cycle.[9] The behavioral assumption that he acts as if to maximize the discounted value of disposable earnings allows the determination of a unique function of $k(t)$. Notice that $k(t)$ is uniquely determined as a result of assuming the economic unit behaves according to well-recognized micro-economic principles. The actual functional form of $k(t)$ is obtained for stage two by the ratio of equation (14) to (15). Once this ratio is formed, it is easily discovered that $k(t)$ is a strictly monotonically decreasing function of time.

At this point, it becomes clear why the constraints force a multiple solution to the maximizing problem, one on the interval $(0, t^*)$ which is called stage one and a second on the interval (t^*, N) which is referred to as stage two. Using the functional form of $k(t)$ defined as above on stage two we find that $k(t)$ will exceed one for all values of t less than t^* or all values of t contained in stage one except t^*. But recalling that $k(t)$ is the proportion of the individual's human capital stock used in the production of more human capital, it is *physically* impossible for $k(t)$ to exceed one. An individual cannot use more than 100 percent of his stock. Apparently, on $(0, t^*)$, the value of a marginal addition to the stock exceeds the cost of making that addition, but the input supply is fixed in each period and will not allow the individual to increase production to the point where the marginal cost of adding more to the stock equals the marginal value of the addition. Figure 4 shows how these constraints operate. The long-run marginal cost (LMC) is the envelope of all short-run marginal cost curves (represented by MC_1, MC_2, MC_3) where it is assumed in Figure 4 that the parameter $b = 1/2$. The problem is that in the first two periods (represented by the subscripts 1, 2), the marginal value of additions to an individual's stock (MV_1 and MV_2) exceed the marginal cost of these additions, but due to the fixed supply of stock in these two periods he cannot produce at the output which would equate these two values. He will, of course, use all his available stock as input in the first two periods, but in the third period the availability of input is no longer a problem. The marginal value of additional stock has been declining with the passage of time (see equation (13)) and in the third period it becomes possible for the individual to equate the marginal cost of production

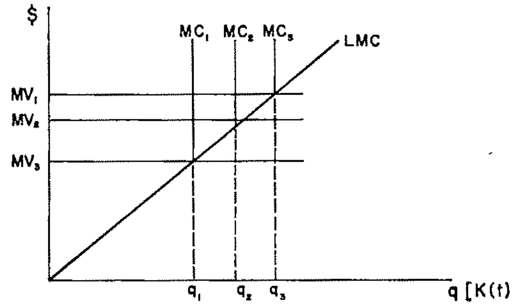

FIGURE 4. OUTPUT CONSTRAINTS WHEN MV OF AN ADDITION TO THE STOCK EXCEEDS MC

[9] At this point it may be worth reemphasizing that the individual has only two alternatives in this model, work and investment in human capital. Clearly leisure is a third alternative which for purposes of this paper is being ignored.

with marginal value of the addition to his stock. Thus, in the third period and all subsequent periods, his production will be constrained by cost considerations rather than an input fixity. The exact time that this switch takes place is represented by t*.

So stage one turns out to be an instance of specialization in production of human capital since the individual will follow a single-minded program of investing to the maximum of his capabilities. He will use his entire stock of human capital as input to the production function and forego all his earning capability during this time. This process will continue until he reaches the point at which the marginal cost of production exceeds the marginal value of that production and production is reduced. The reduced production will be observable as an increase in the amount of human capital the individual is willing to rent in the labor market.

It is now possible to define $K(\mathrm{t})$, $E(\mathrm{t})$, $k(\mathrm{t})$, and $Y(\mathrm{t})$ over the entire earning life cycle. This provides an opportunity to summarize all the important functions discussed above. All symbols used are as previously defined and $b=1/2$.

The path of human capital stock used to produce more human capital over the life cycle is[10]

$$(18)\qquad K(\mathrm{t}) = \begin{cases} E(\mathrm{t}), & 0 \leq \mathrm{t} \leq \mathrm{t}^* \\ \dfrac{\beta^2}{4(r+\delta)^2}\left[1 - e^{(r+\delta)(\mathrm{t}-N)}\right]^2, & \mathrm{t}^* \leq \mathrm{t} \leq N \end{cases}$$

Recalling that

$$B = \left[\frac{\beta}{\delta} + \left(E_0{}^{1/2} - \frac{\beta}{\delta}\right)e^{-\delta \mathrm{t}^*/2}\right]^2 e^{\delta \mathrm{t}^*} - \frac{\beta^2}{2\delta(r+\delta)}\left[1 - \frac{\delta}{r+2\delta}e^{(r+\delta)(\mathrm{t}^*-N)}\right]e^{\delta \mathrm{t}^*}$$

the optimal path for total human capital accumulation is given by equation (19). The proportion of human capital devoted to the production of more human capital is given by equation (20), and the optimal earnings path over the life cycle is given by (21).

[10] An appendix of these derivations will be provided upon request.

$$(19)\qquad E(\mathrm{t}) = \begin{cases} \left[\dfrac{\beta}{\delta} + \left(E_0{}^{1/2} - \dfrac{\beta}{\delta}\right)e^{-\delta \mathrm{t}/2}\right]^2, & 0 \leq \mathrm{t} \leq \mathrm{t}^* \\ Be^{-\delta \mathrm{t}} + \dfrac{\beta^2}{2\delta(r+\delta)}\left[1 - \dfrac{\delta}{r+2\delta}e^{(r+\delta)(\mathrm{t}-N)}\right], & \mathrm{t}^* \leq \mathrm{t} \leq N \end{cases}$$

$$(20)\qquad k(\mathrm{t}) = \begin{cases} 1.0, & 0 \leq \mathrm{t} \leq \mathrm{t}^* \\ \dfrac{\dfrac{\beta^2}{4(r+\delta)^2}\left[1 - e^{(r+\delta)(\mathrm{t}-N)}\right]^2}{Be^{-\delta \mathrm{t}} + \dfrac{\beta^2}{2\delta(r+\delta)}\left[1 - \dfrac{\delta}{r+2\delta}e^{(r+\delta)(\mathrm{t}-N)}\right]}, & \mathrm{t}^* \leq \mathrm{t} \leq N \end{cases}$$

$$(21)\qquad Y(\mathrm{t}) = \begin{cases} 0.0, & 0 \leq \mathrm{t} \leq \mathrm{t}^* \\ \dfrac{R\beta^2(2r+\delta)}{4\delta(r+\delta)^2} + RBe^{-\delta \mathrm{t}} + \dfrac{R\beta^2}{2(r+\delta)^2}\left(\dfrac{\delta}{(r+2\delta)} - \dfrac{1}{2}e^{(r+\delta)(\mathrm{t}-N)}\right)e^{(r+\delta)(\mathrm{t}-N)}, & \mathrm{t}^* \leq \mathrm{t} \leq N \end{cases}$$

The model is a function of essentially four parameters and an initial stock of human capital, which will be referred to as a parameter in all subsequent discussions. Since the rental rate, R, is essentially a factor of proportionality and has an unambiguous effect, the approach will be to discuss the other four parameters as they affect the capital accumulation path and the path of capital input. In particular, the effect of these four parameters on the length of time the individual spends specializing in the production of human capital and on the location of the time period in which the human capital accumulation path attains its maximum value will be discussed. Special attention will be given to $K(t)$ and $E(t)$ since they in turn determine the effect of parameter variations on $k(t)$ and $Y(t)$.

Figure 5 is a graphical picture of the shapes of $K(t)$, $E(t)$, and $k(t)$. Notice that the value of $E(t)$ and $K(t)$ is to be read off the left vertical axis and the value of $k(t)$ is to be read off the right vertical axis. The disposable earnings stream, $Y(t)$, will be discussed later.

One of the important characteristics of the model is the fact that t^*, the point when the individual stops specialization in the production of human capital, is determined endogenously as can be seen from Figure 5. Also, notice that the time when the stock of human capital is maximum occurs at t_m. At time t_m the rate at which the stock depreciates equals the rate at which it is being produced.[11] This is not a

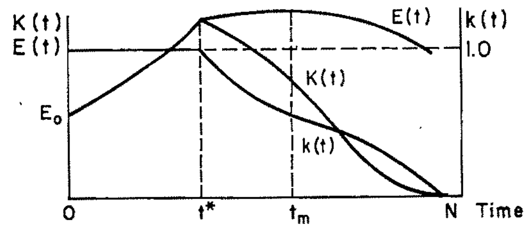

FIGURE 5. A GRAPH OF $E(t)$, $K(t)$, AND $k(t)$

particularly unusual result[12] and is explained by the fact that sometime after specialization in production stops the depreciated human capital exceeds the amount of newly produced human capital and $q[k(t)]$ becomes less than $\delta E(t)$ making $\dot{E}(t)$ in equation (8) negative. The point in time when $\dot{E}(t)$ goes from positive to negative is t_m.

Since the effects of β, the ability-to-produce parameter, and E_0, the initial endowment of human capital, on t^* are most interesting, let us discuss these first. By noticing that during stage two of the life cycle, (t^*, N), $K(t)$ is independent of E_0, it can be seen from Figure 5 that *ceteris paribus*, the larger one's initial endowment of human capital, the earlier he will stop specializing in the production of human capital and begin earning positive income. Further, the greater the ability index, β, the longer the period of specialization, other things constant. The size of one's initial endowment and his ability to produce tend to operate in different directions with respect to the length of time spent specializing in the production of human capital and the outcome is not clear a priori. This is contrary to previous theories.[13]

[11] To show that the maximum occurs at t_m, the first derivative of equation (19) on (t^*, N) obtains,

$$E'(t) = -\delta B e^{-\delta t} - \frac{\beta^2}{2(r+2\delta)} e^{(r+\delta)(t-N)}$$

The usual procedure is to set $E'(t)=0$ and solve for t. Since the second term on the right-hand side of $E'(t)$ is strictly negative for all values of t, in order for a maximum to exist in the interior of the interval (t^*, N), B must be negative. The sign of B is not at all easy to establish analytically, but can be established by using a computer to compute B for various parameter values. This was done, and it was found that B is indeed negative. Therefore, $E(t)$ has a maximum value in the interior of (t^*, N).

[12] See Becker (Appendix B) for a somewhat different view of how the stock of human capital is accumulated. However, he also concludes the stock path attains a maximum after full time investment has stopped.

[13] See Ben-Porath (1967, p. 358). Also, Weiss (1971a) criticized Mincer (1970) for assuming ability to be

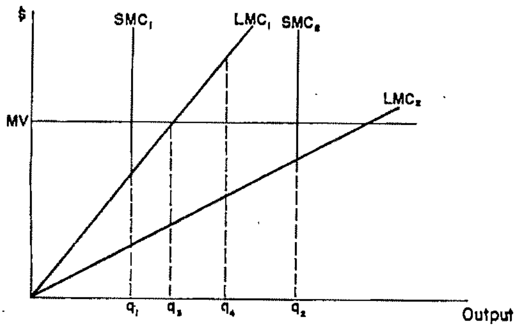

FIGURE 6. EFFECT OF E_0 AND β ON PRODUCTION

The phenomenon described above can be shown most clearly by considering two individuals who are identical except in their ability to produce human capital as shown by Figure 6. Since the higher the β the lower the marginal cost curve, individual 1, with LMC_1, will have a smaller ability index than individual 2. If the output using all the initial endowment as input for both individuals were q_2, then individual 1 would not specialize, producing at q_3, whereas individual 2 would specialize, producing at q_2. Clearly, the size of the ability index, β, is positively related to the time t* when specialization stops.

Now consider two individuals who are identical except for their initial endowment of human capital. In this case, let individual 1 have the smaller endowment. If he used it all for production, he could produce output q_1. Individual 2, on the other hand, could produce output q_4 if he used his entire initial endowment for production. If LMC_1 represents the long-run marginal costs for both individuals, 1 is faced with a short-run factor fixity and will specialize in production, whereas 2 will equate MV with LMC_1 at q_3, an output which is not constrained by an input fixity. Thus, individual 2 will not specialize and E_0 is negatively related to t*.[14]

The rate of discount will be inversely related to the time spent specializing. This result makes eminently good sense. The higher the discount rate, the less value an individual places on future dollars relative to present dollars. The individual with the relatively higher discount rate will be less inclined to forego present income for investment purposes than would the individual with a relatively low discount rate. Therefore, if all other parameters are the same, the individual with the higher discount rate will stop specializing in the production of human capital sooner than the individual with a lower discount rate.

Finally, an increase in the rate of depreciation will decrease the length of the period of specialization. The economic argument here is very analogous to that given above for the discount rate. The individual will have a larger present value of actual earnings if he places more importance on earnings early rather than later in the planning horizon because a high depreciation rate will eat away more of his stock of human capital late in the planning horizon than will a low depreciation rate. Early earnings will be more important in the objective function with a high rate of depreciation than with a low rate of depreciation, other things the same.[15]

The optimal disposable earnings path represented by equation (21) has a shape which is at first increasing, then begins to

positively related to t*. According to Weiss' model, ability can be either positive or negatively related to t*.

[14] These results are both independent of the assumption that $b=1/2$ as long as b is the same between individuals and is not equal to one or zero. If b is not equal between individuals the results may not hold.

[15] Analytically this proposition is not easily established. The difficulty is that $K(t)$ is negatively related to δ on both (0, t*) and (t*, N). In Figure 5 the reader can imagine both segments of $K(t)$ swinging downward. The location of t* depends on which segment has the larger relative shift for a given increase in the rate of depreciation. By computer simulation it was determined that the segment of $K(t)$ on (t*, N) shifted down relatively more than $K(t)$ on (0, t*) giving the result that an increased rate of depreciation decreased the interval of specialization, *ceteris paribus*. See my dissertation for these and other simulation results.

decrease after attaining a maximum. The maximum of the disposable earnings path is attained later in the life cycle than is the maximum of the human capital stock.[16]

The path of proportion of earning capacity foregone function $k(t)$, is displayed in Figure 5. A quick comparison of this function with the one used by Johnson represented by Figure 2 shows some substantial differences. In addition to the obvious differences in second order properties, the function generated by this model shows no notch at t^* (or S in Johnson's terminology). Johnson had no theoretical reason for a priori assuming $k(t)$ to be discontinuous at t^*. This was simply an empirical result which made his model fit the data better than a sectionally continuous $k(t)$ implied by this model. This empirical test may be an illusion created by the fact that using the end of formal schooling as t^* is incorrect. Possibly t^* occurs substantially before that time and using S rather than the true t^* causes the discontinuity.

If, however, S is a reasonable measure of t^*, this may be evidence of what Ben-Porath (1970) described as nonneutral human capital accumulation. Simply stated, it means that human capital produced after t^* has less value, after adjustment for the fact that it is produced later in the life cycle, than that produced before t^*. The neutrality hypothesis poses a serious question and it would appear that this is at least one way of considering it.

[16] One case in which the two paths, $Y(t)$ and $E(t)$, obtain maxima at the same time is when the scale parameter b is one. When $b=1$ the marginal cost schedule is constant and the individual will specialize as long as the marginal value of additional stock exceeds the marginal cost of production, but when the reverse is true, *all* production stops and the individual rents his entire stock in the labor market. This would imply a $k(t)$ that is constant at one until t^* and is constant at zero for all t after t^*. Clearly both $Y(t)$ and $E(t)$ would attain maxima at t^*. Ben-Porath (1967) also observed this limiting behavior.

III. Predicted Training Costs

The choice variable in this model is the function which describes the amount of human capital allocated to the production of new human capital over the life cycle, $K(t)$. Clearly the cost of training will be the product $RK(t)$. As such, it is of fundamental importance to establish the empirical validity of the shape of this function as predicted from the model. If the general shape of $K(t)$ is found to be insupportable empirically, the entire model is questionable, since all functions were derived from $K(t)$.

The most complete work to date on empirically estimating on-the-job-training (*OJT*) costs is by Mincer (1962). Using a version of equation (1) which assumed the rates of return were equal across investments, Mincer calculated the additional training costs, both formal and *OJT*, associated with (a), the marginal decision to complete high school if elementary school has been completed, and (b) the marginal decision to complete college if high school has been completed. The procedure used to obtain estimates of these costs year-by-year was first to calculate the internal rate of return to each marginal decision and assume this rate of return represented the rate of return to both schooling and *OJT*.[17]

Table 1 lists all the schooling and *OJT* costs of high school and college graduates over the life cycle for the years 1939, 1949, and 1958. The underline indicates where schooling costs stop and *OJT* costs start, which for high school graduates is age 17, and for college graduates is age 21. The costs listed for high school graduates are the additional training costs incurred by individuals who complete high school over and above those incurred by individuals who have completed elementary school.

[17] Mincer's data were not designed for the sort of test made here, since he was interested in the total marginal cost of the decision rather than year-by-year marginal cost.

The costs listed under college graduates are marginal to the decision to go to college given high school has been completed.

The counterpart to Mincer's estimates of marginal training costs would be the difference $R_1K_1(t)-R_2K_2(t)$ in the model presented here. The terms R_1 and R_2 are the rental rates of a college graduate and a high school graduate, respectively, and $K_1(t)$ and $K_2(t)$ are the respective amounts of human capital used in production over the life cycle. Notice that the above difference measures the additional cost of investment associated with the marginal decision to complete college given high school has been completed. The marginal training costs will be proportional to

$$H(t) = K_1(t) - K_2(t) \tag{22}$$

If $H(t)$ is to predict training costs (up to a factor of proportionality), it should, in general, display properties similar to those displayed by Mincer's data. The shape of $H(t)$ can be mathematically determined on the intervals (t_2^*, t_1^*) and (t_1^*, N) where it is assumed that both groups stop earning at age N. On (t_2^*, t_1^*) the individuals represented by $K_2(t)$ will not be specializing in the production of human capital, whereas the individuals

represented by $K_1(t)$ are still specializing. On this interval, $H(t)$ is increasing at an increasing rate.

On the interval (t_1^*, N) both groups of individuals have stopped specializing and $H(t)$ declines at an increasing rate until just before year N, $H(t)$ starts declining at a decreasing rate. Since the observed differences would become extremely small toward the end of the life cycle, we would not expect to see $H(t)$ decline at a decreasing rate. As can be seen from Table 1, Mincer did not observe differences past age 44.[18]

Thus, this model predicts the signs on both first and second differences of Mincer's data. In particular it predicts that over the interval (t_2^*, t_1^*), both first and second differences should be positive and over the interval (t_1^*, N), both first and second differences should be negative. In looking at the marginal decision to complete high school, t_2^*, is 14 years of age and t_1^* is 17. When the marginal decision to complete college is under consideration, t_2^* is 17 and t_1^* is 21.

[18] It is this fact that leads Ben-Porath (1970) to think individuals may well produce human capital in a nonneutral fashion. He also used Mincer's data.

All the signs of first and second differences are summarized in Table 2. Over the interval (t_2^*, t_1^*), we have a total of 18 first differences taking both high school and college together. All were correctly predicted. On the interval (t_1^*, N) or what is entitled *OJT*, we have a total of 130 first differences of which 121 were correctly predicted.

Again taking both high school and college together, we have a total of 12 second differences on (t_2^*, t_1^*) or what is labeled school. All but one of these were correctly predicted. On (t_1^*, N) there are 113 second differences of which 88 were correctly predicted. Taken individually, in 1949 the null hypothesis that the signs of second differences on (t_1^*, N) were random could not be rejected by a standard chi-square test. In all other cases this null hypothesis was rejected.

IV. Variations in the Period of Specialization

One of the important numbers produced by this model from a given combination of parameter values is the time, t^*, when an individual stops specializing in the production of human capital and begins renting

part of his stock in the labor market. Traditionally, empirical studies have taken this number to be the time when an individual completes formal schooling. In this model, however, t* is interpreted as being the point in time in the investor's life cycle when he ceases to devote 100 percent of his time to the production of human capital. One observation that can be made from the model is that when specialization stops, training does not stop but continues at a decreasing rate. An individual who does not find it optimal to specialize, even if he is in school, will search for work which can accommodate his investment activities and yield income. The question then becomes one of who will shorten the period of specialization by beginning to participate in the labor force.

To get at this question in a way which will test the model we must make some assumptions. The groups used to make the test are white and nonwhite teenagers between 14 and 19 who are attending high school.[19] The assumptions made are that the rate at which human capital depreciates, the rate at which future income is discounted, and the ability to produce is the same on average across any race, sex, or age stratification of teenagers attending school. In other words, in our model, r, δ, and β are assumed to be about equal across any race, sex, or age stratification on average.[20]

With this assumption, the distinctive feature between or within stratifications will be differences in the initial endowment of human capital. One's initial endowment is a single number which summarizes a number of principle components. It is argued here that two such principle components which are very important are family income and family size. Surely there are other environmental effects which are important, but our attention will be directed to these two for the test which follows.

The individual's initial stock, in a sense, determines his relative protagonism toward his stock of human capital. The more conducive is his environment to producing human capital, the larger will be E_0. Family income influences several variables which might create an environment relatively helpful in the production of human capital. Such things as space, privacy, cultural activities, and relatively well-educated parents would be more likely to be present in relatively high income families, and would be associated with a more conducive environment to produce human capital.

A relatively large family, on the other hand, would tend to compete with many of these things as well as with the time parents could spend giving an individual personal attention. Family size would, therefore, tend to have a negative influence on E_0. It seems, however, that since family income can substitute for many of the negative effects of family size, income would be the more reliable indicator of the size of E_0. Certainly it would be expected that the higher the family income, the less important the family size.

The model proposed here predicts that other things constant, the larger one's initial endowment of human capital, the sooner will he stop specializing in the production of human capital. Translated into the variables described above, the larger one's family income is or the smaller one's family size is, the sooner he will begin participating in the labor force.

Since black families tend to be larger than white families and have smaller incomes, we would expect to see a smaller percentage of black teenagers who are attending school participating in the labor

[19] Notice that dropouts are not included.

[20] The existence of market imperfections in the investment market may create problems with this assumption if they are directed at a particular subset of the population. The empirical evidence is not clear cut on this point.

TABLE 3—THE AVERAGE LABOR FORCE PARTICIPATION RATE OF TEENAGERS, ENROLLED IN SCHOOL, BY AGE, COLOR, AND SEX

	Whites		Nonwhites

Source: Fearn.

force at any given age.[21] Table 3 shows data taken from Robert Fearn which does tend to confirm our hypothesis.

However, this test is not a particularly strong one because the rate of unemployment among black teenagers is relatively high. It may be that the high rate of unemployment forces black teenage students to continue specialization involuntarily. To get around the problem we can look at Fearn's regressions which adjust for unemployment and wage rates as well as family size and income. We can no longer make across strata comparisons, but it still should be true that within a particular age, sex, race category, income should be positively related and family size negatively related to labor force participation.

Table 4 summarizes these regressions and we find that our hypothesis is still true among nonwhites, but not among whites. As pointed out above, it is suspected that family income will become more important than family size as income increases. Further, it is also suspected that at constant family income, as family size increases its effect will become more important. Given that nonwhites have larger

[a] Labor force participation rate is the dependent variable.

families and smaller incomes than whites, it is to be expected that family size would be more important in determining the length of the period of specialization of nonwhites. For this reason, it would seem that the negative effect of family size on labor force participation rates among nonwhites is not spurious.

V. Conclusions

At the end of Section I in this paper, a number of questions were asked about the shape of $k(t)$ over the life cycle if the individual chose $k(t)$ within some choice theoretic framework as it would appear he must do. From the model presented in Section II, a particular $k(t)$ is implied which does not demonstrate all the characteristics shown in Figure 2. Although $k(t)$ is equal to one in the beginning of the life cycle and declines after specialization stops, the resemblance ends there. The function describing the proportion of human capital allocated to production in the model presented here neither has a notch at the time specialization stops nor does it decline at a constant rate. Rather, there is a fairly smooth transition from specialization to nonspecialization and during the period of nonspecialization, $k(t)$ declines first at an increasing rate, then at a decreasing rate.

[21] The average white family had 1.27 children under age 18 whereas the average Negro family had 1.80, in 1969. Only 8.9 percent of white families had a female head whereas 28.6 percent of Negro families were headed by a female. See U.S. Bureau of Census (Table 45, p. 38).

The shape of $k(t)$ is determined by the way which the individual allocates his stock of human capital between production and earning. This process is described by the function $K(t)$. Empirical evidence indicates that the shape of training costs marginal to the next best alternative are predicted reasonably well. Since these marginal costs depend on the shape of $K(t)$ quite directly, possibly the model describes the process at least in gross sense.

A second test was carried out on the important question of how investors react to a change in the initial endowment of human capital as measured by the proxy variables of family income and family size. The results indicate that investors do tend to spend less time specializing in production as the initial stock gets larger, other things the same. This result indicates that taking the time when formal schooling ends as the time when specialization stops may not be entirely accurate in the case of high school and college graduates.[22]

Inherent Advantage, Costs, and Resource Allocation in the Transportation Industry

By ROSALIND S. SENECA*

The interpretation of the term "inherent advantage" when applied to competing modes of transportation has been the subject of some controversy. It first appears in the Declaration of National Transportation Policy (*NTP*) in the Transportation Act of 1940 which states that the regulatory authorities (Congress, the Commissions, and the Courts) should ensure that traffic is allocated between modes in such a way as to "recognize and preserve the inherent advantages of each," and should also prevent "destructive competition" between modes. The terms inherent advantage and destructive competition are not defined in the Declaration. However, in an amendment to the rules of rate making which appears as Section 15 a(3), the Interstate Commerce Act states that "rates of a carrier shall not be held up to a particular level to protect the traffic of any other mode of transportation, giving due consideration to the objectives of the National Transportation Policy."

A study of the interpretation of the law by the Interstate Commerce Commission (*ICC*) reveals that the *ICC* has tended to interpret inherent advantage to mean lowest average cost, and has sometimes prevented modes with low marginal costs from lowering prices to the marginal cost floor when this would divert traffic from the mode with the lowest average cost (see Robert Harbeson). The *ICC* has also accepted the argument that in determining the price to be charged by any one mode, the costs of that mode alone should be referred to, the costs of the competing modes being irrelevant.

Economists define destructive competition as occurring only when one mode attempts to capture the traffic of a competitor by pricing below marginal cost, and some maintain that, being an irrational market strategy, destructive competition is unlikely to occur (see for example John McGee).[1] However, the *ICC* has evidently been concerned with preventing the demise of any existing mode, and the tendency has been to interpret as destructive competition any price policy of a competitor which diverts traffic away from the mode with the lowest average cost.[2] Indeed, the equity issue of the survival of competing modes has played an important part in the decisions of the regulatory authorities (see Ronald Coase).

In the theoretical literature the question of the determination of the optimal allocation of traffic between transportation modes has been dominated by the marginal cost pricing controversy. A policy of setting rates equal to marginal costs has been

* Assistant professor of economics, Hunter College of the City University of New York. This paper is taken from a dissertation completed at the University of Pennsylvania. I should like to thank O. E. Williamson, C. Caton, J. J. Seneca, G. D. N. Worswick, P. Davidson, D. F. Bradford, and the referee for helpful comments.

[1] Sydney Weintraub, p. 193, presents contrary argument.

[2] An important recent example is the Ingot Molds case in which the Supreme Court decided *not* to allow the railroads to reduce their rates for carrying Ingot Molds to equal that of the barges, a strategy which would enable the railroads to compete for the traffic. The barge average cost was below that of the railroads, but the railroads had the lower marginal cost.

supported on the grounds that it possesses attractive efficiency properties (restated in a recent article by William Baumol and David Bradford). The main objections to such a policy have been 1) that second best considerations destroy its theoretical justification; 2) that where decreasing costs prevail and prices are set equal to marginal costs total costs will not be covered; and 3) that the difficulty of estimating marginal cost makes the practical operation of a marginal cost pricing policy infeasible.

An examination of the testimony presented by several leading economists in the current *ICC* investigation into "Cost Standards in Intermodal Rate Proceedings" reveals continuing differences on this subject. While there is agreement that the function of regulation under the concept of inherent advantage is to permit an allocation of traffic between modes which minimizes the total cost of providing transportation service (indeed "safe, adequate, *economical* and *efficient* service" was a stated goal in the *NTP*) separate arguments are made in favor of allocating traffic 1) to the mode with the lowest "long-run variable cost" (Baumol, 1970); 2) to the mode with the lowest "long-run incremental cost" (Leon Moses); 3) to the mode with the lowest "out-of-pocket cost" (Merton Peck). Peck defines out-of-pocket cost as long-run variable cost, but the term has also been defined elsewhere as meaning "short-run marginal cost" (George Borts).

However Borts alone makes explicit the following important point: namely that there is a serious deficiency in the use of marginal costs to allocate traffic among competing modes, a deficiency which arises because of the failure to take account of differences between the total costs of competing modes. Allocating traffic to the mode with the lowest long-run marginal cost will not *necessarily* minimize the total cost of providing the service.

The purpose of this paper is to provide a further clarification of these issues. In Section I a model is presented for determining the optimal allocation of traffic between two competing modes, where the objective is to minimize the total costs of transporting a fixed amount of a single commodity between two points. The role and importance of total and marginal costs in attaining a solution to the cost-minimization problem is identified. An efficient allocation of resources can only be found by considering the transportation industry as a whole, the cost curves for all modes and the total demand for transportation, and *not* by looking at cost and demand relationships for each mode separately. In Section II an extension of the model is indicated for consideration of the question of optimal price policy when demand for transportation is not perfectly inelastic but represented as a downward-sloping schedule, and also when a profit constraint is imposed for the industry. Section III contains the conclusions which can be drawn from the models.

I

Model 1

Assume that the transportation industry consists of two modes of transportation both operating between the same two geographic points. Assume further that the cost characteristics of a transportation mode can be put in one of two categories:[3]

Category I: The mode operates with short-lived facilities and highly flexible organization. This means all short-run fixed costs are of a transitory nature and can be transformed quickly into incremental costs. Long-run marginal costs include incremental capacity costs and tend to be increasing over the relevant range. (The

[3] See for example Baumol et al. for a fuller analysis of transportation costs.

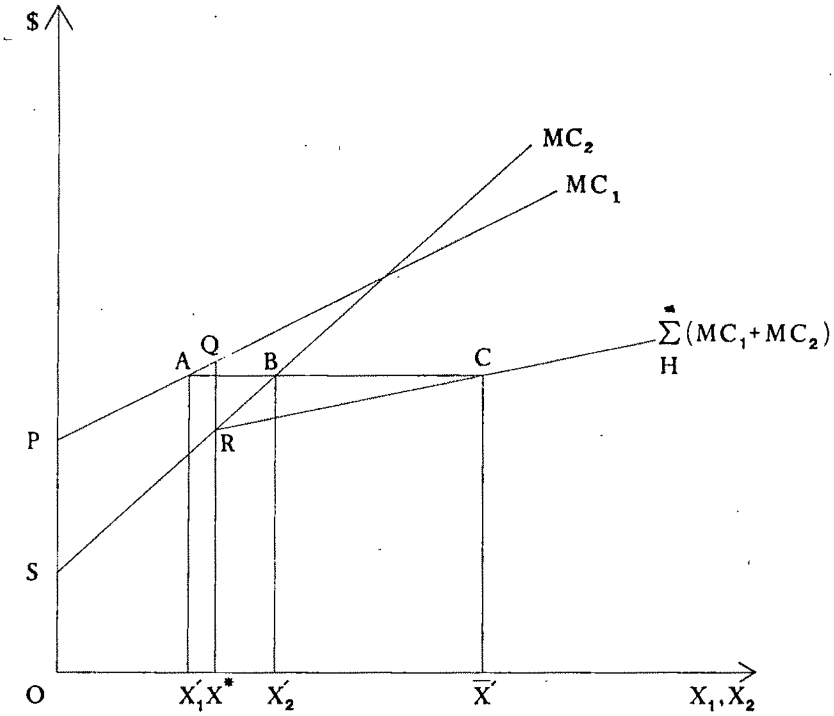

FIGURE 1

trucking industry might fall into this category.)

Category II: The technology of the mode is characterized by large amounts of sunk physical investments in long-lived facilities which are not generally transferable to other uses without great loss. This is typical of the railroads. The result is that, while some capacity costs (e.g. depreciation, cost of capital) should be included in long-run marginal costs, an indefinitely long-term view of incremental costs is not appropriate, and a large proportion of fixed costs may be expected to remain fixed over any contemplated planning horizon. Long-run marginal costs therefore tend to be decreasing over the relevant output range.[4]

[4] There is disagreement over the question of whether or not the railroads in fact operate on the declining portion of their long-run marginal cost curve. Moses and J. R. Meyer et al. suggest that the railroads do operate under increasing returns. Borts disputes this.

Suppose now that there is one commodity, X, to be carried and the demand for X is unresponsive to price changes and fixed at a given level $\bar{X}$. The objective is to minimize the total cost of transporting $\bar{X}$ between two points and to determine how much of $\bar{X}$ should optimally be carried by mode 1 and how much by mode 2.[5]

Case 1: Consider first the case in which both modes fall into Category I. Then the long-run marginal cost curves of mode 1 and mode 2 can be represented by the increasing curves MC_1 and MC_2 in Figure 1. Suppose $\bar{X} < X^*$ then the *total* cost of loading $\bar{X}$ onto mode 2, shown by area $OSRX^*$

[5] A formal presentation of the following models is made in the Appendix to this paper in which necessary and sufficient conditions for cost minimization are given for those cases presented in the text.

is less than the total cost of loading $\overline{X}$ onto mode 1, shown by area $OPQX^*$.[6] All of $\overline{X}$ should be carried by mode 2, mode 1 is not activated. Note also that for $\overline{X}<X^*$, $MC_2<MC_1$. If $\overline{X}$ exceeds X^*, the total transportation cost can be minimized by activating mode 1 and sharing the commodity between the modes. Now the share of $\overline{X}$ to be carried by each mode is determined such that MC_1 and MC_2 are equal, and is found in the following way. Starting from point R the marginal cost curves MC_1 and MC_2 are added horizontally to derive the curve labelled $\sum_H (MC_1+MC_2)$ in Figure 1, where $\sum_H$ denotes "horizontal sum." This summed MC curve measures the opportunity cost of carrying each level of $\overline{X}$. For example, where $\overline{X}$ equals $\overline{X}'$ the opportunity cost of carrying $\overline{X}'$ is given by C on the summed curve. At the level C the marginal costs for each mode are equal, at A for mode 1 and at B for mode 2. The share of $\overline{X}'$ carried by mode 1 is X_1' and the share carried by mode 2 is X_2'. Note that for different levels of demand the optimal division of $\overline{X}$ between the two modes changes. Whether one or both modes should be used does not therefore depend wholly on their cost curves but also on the scale of demand.

Case 2: Consider now a second case in which both modes fall into Category II. Both modes have decreasing long-run marginal cost curves, MC_1 and MC_2 in Figure 2. Suppose $\overline{X}$ is to be carried. At $\overline{X}$, MC_2 lies below MC_1. However this does not necessarily mean that $\overline{X}$ should all be carried on mode 2, since, for lower values of X, a portion of the MC_2 curve lies above the MC_1 curve. Only a comparison of the areas under the curves, i.e., of total costs, can determine whether $\overline{X}$ should be carried on

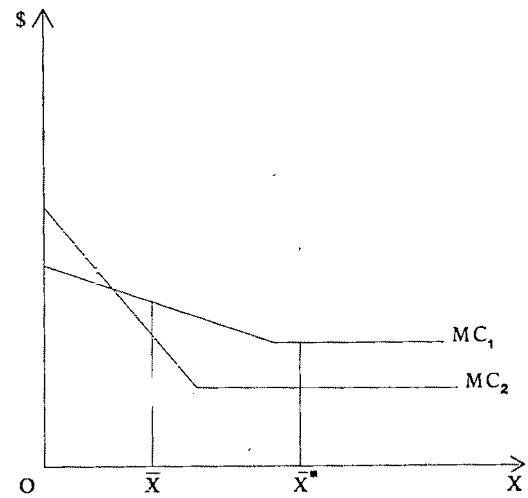

FIGURE 2

mode 1 or mode 2. Also in this case the commodity will never be divided between the modes, regardless of the value of $\overline{X}$, but will always be carried by one mode alone. For example at $\overline{X}$ in Figure 2, TC_1 is less than TC_2 (where TC=total cost), and so all of $\overline{X}$ will be carried by mode 1. When $\overline{X}^*$ is to be carried, TC_2 is just less than TC_1 and so all the commodity will be carried by mode 2. Because both cost curves are decreasing, it is never efficient to shift small amounts of the commodity between the modes since the lower costs can only be taken advantage of if large amounts are carried. The opposite of this is true in Case 1 where small amounts can be carried at lower cost than large amounts.

Case 3: Assume now that mode 1 has an increasing long-run marginal cost curve and mode 2 a long-run marginal cost curve which decreases and asymptotically approaches a constant level above zero. Assume further that MC_2 decreases at a slower rate than MC_1 increases (see Figure 3). Suppose the fixed demand is relatively small. If $\overline{X}\leq X_2$ then $TC_1<TC_2$, since $A_2<A_1$. When mode 1 carries X_2 its marginal cost is just equal by construction to

[6] Since all relevant costs are considered variable in the long run, the area under the marginal cost curve at any output level is a correct measure of the *total* cost of transporting that level of output.

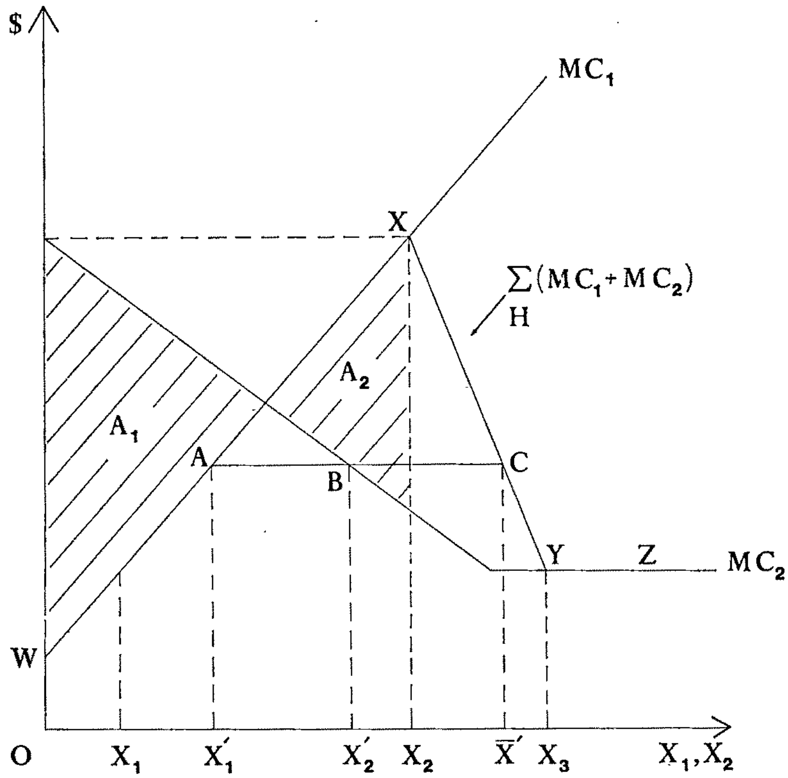

FIGURE 3

the marginal cost on mode 2 at the vertical axis. Therefore, for any $\overline{X}>X_2$, the total transportation cost can be minimized by activating the second mode and taking advantage of the fact that its marginal cost decreases by allocating to it an increasing share of $\overline{X}$. Note that in this case it is cost minimizing to start sharing the commodity between the modes at a *lower* value of $\overline{X}$ than that at which $TC_1=TC_2$, i.e., *before* $\overline{X}$ reaches that level at which $A_1=A_2$.

Now the share of $\overline{X}$ to be carried by each mode is determined such that MC_1 and MC_2 are equal and is found by adding the curves MC_1 and MC_2 horizontally, starting from point X, to derive the forward sloping curve labelled $\sum_H (MC_1+MC_2)$ in Figure 3. As before, this summed MC curve measures the opportunity cost of carrying each level of $\overline{X}$. If $\overline{X}=\overline{X}'$ in Figure 3 the opportunity cost of carrying $\overline{X}'$ is given by C on the summed curve, and the share of $\overline{X}'$ to be carried by modes 1 and 2 equals X_1' and X_2', respectively, since these amounts can be carried at equal marginal cost. Further inspection of Figure 3 shows that the nearer the value $\overline{X}$ is to X_3 the larger the share of commodity loaded onto mode 2, the smaller the share loaded onto mode 1 and the lower the marginal cost of transporting the commodity. If $\overline{X}$ exceeds X_3 then only X_1 is loaded onto mode 1 and all the rest onto mode 2, since additional quantities of commodity can be loaded onto mode 2 at constant marginal cost. The composite curve $WXYZ$ therefore measures the marginal cost of carrying the commodity at every level of $\overline{X}$.

For the case in which the marginal cost

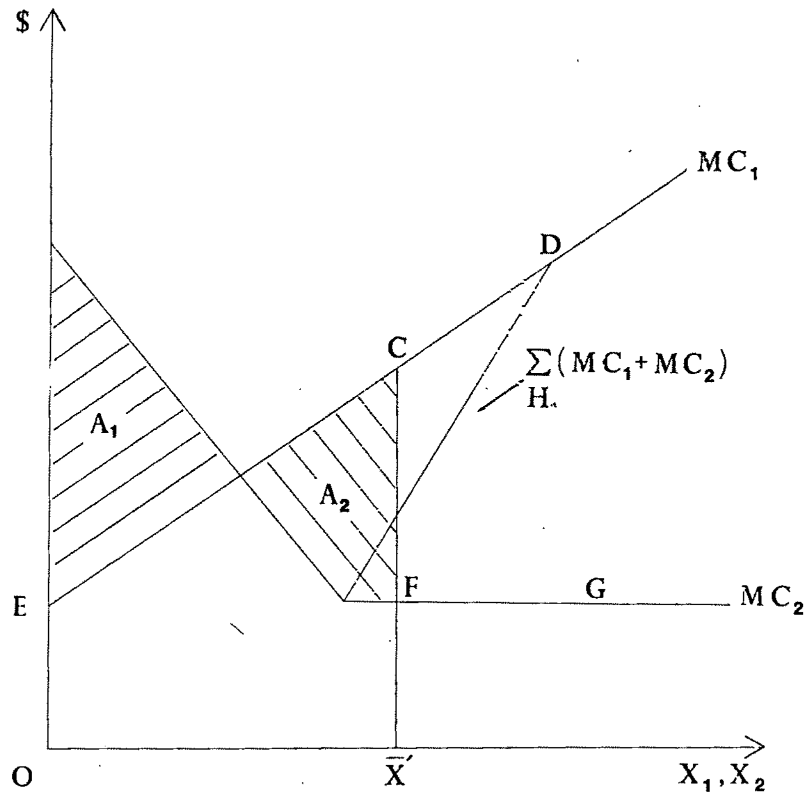

FIGURE 4

curve for mode 1 increases at a slower rate than the marginal cost curve for mode 2 decreases the summed MC curve is backward sloping (see Figure 4). For low values of $\overline{X}$ the total transportation cost is minimized by using mode 1 alone. However there is a value for $\overline{X}$, say $\overline{X}'$, at which the area under the MC_1 curve is precisely equal to the area under the MC_2 curve, i.e., $A_1 = A_2$. At higher output levels $A_2 > A_1$ and hence at $\overline{X}'$ all of the commodity should be shifted onto mode 2. This point occurs *before* the marginal cost of carrying one extra unit of commodity by mode 1 equals the marginal cost of carrying the first unit of commodity by mode 2, point D in Figure 4. Further we can say that at no point is the backward-bending part of the summed MC curve used to determine the amounts of commodity carried by each mode. The marginal cost of transporting each level of X is shown by the discontinuous curve $ECFG$, the discontinuity occurring as mode 2 is brought into operation at $\overline{X}'$.

II

Model 2

In this section the model is extended: the assumption that the demand for transportation is fixed and unresponsive to price changes is dropped and the model redefined using a downward sloping demand schedule for transportation.

Assume that the transportation industry consists of two modes with the same cost characteristics as described in Case 3 above. A single firm's demand curve for transportation is derived from the demand for the commodity produced by the firm.

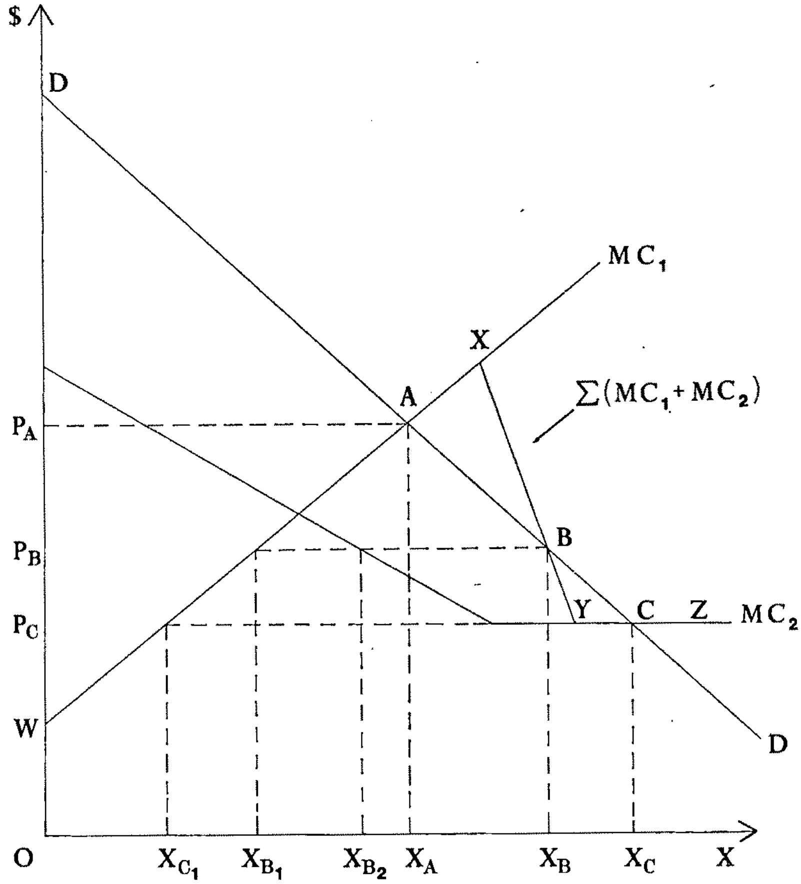

FIGURE 5

A firm requires transportation for the commodity between two points and this transportation requirement therefore appears as an input in the firm's production function. From the profit-maximizing calculation of the firm we can derive its demand curve for transportation, and, assuming perfect competition, we can express the total demand for transportation by all firms in an industry as $P=G(X)$, where $P=$price of transportation and $X=$the number of units of commodity to be transported.[7] The demand curve is shown as *DD* in Figure 5.

[7] Note that although there are two modes the demand for transportation depends on a *single* transportation price. The underlying assumption is that industry considers the two modes to be perfect substitutes and so will always choose the lowest priced mode.

Now the objective is to maximize the social welfare derived from the productive activity of the transportation industry. We shall use the conventional partial equilibrium social welfare function whereby if it is assumed that all of the optimum conditions of production and exchange are satisfied elsewhere in the economy, social benefit (*SB*) is given by total revenue (*TR*) plus consumers' surplus (*CS*), and social cost (*SC*) is separable into total pecuniary cost less intramarginal rent. Assuming that all factors are available to each mode in completely elastic supply, intramarginal rents will be zero and the net welfare gain is:

$$W = SB - SC = TR + S - TC$$

The necessary conditions for maximiz-

ing W are found to be $P=MC_1=MC_2$, i.e., the total amount of commodity carried, and the division of the commodity between each mode are determined such that price equals the marginal cost of carrying the commodity on each mode.[8]

Using the cost curves MC_1 and MC_2 described in Figure 3 we know that the composite curve $WXYZ$ measures the marginal opportunity cost of carrying each different amount of commodity. We now introduce the downward-sloping demand schedule DD and observe that it intersects the composite cost curve at three points—A, B, and C in Figure 5. Thus, one of three prices could be charged. If P_A were charged, X_A would be demanded and only mode 1 would be activated. If P_B were charged, X_B would be demanded; mode 1 would carry X_{B1} and mode 2 would carry X_{B2}. If P_C were charged X_C would be demanded; mode 1 would carry X_{C1} and the rest would be carried by mode 2.

Of all three points A, B, and C, that price is chosen which yields the largest value of W. This can *only* be found by comparing the appropriate areas under the demand and cost curves. Once again reference to marginal costs alone is insufficient for determining the optimal price and allocation of commodity between modes, total costs must be referred to in the solution.

Model 3

Suppose now that the condition is made that the total revenues received by the transportation industry as a whole must exceed the total costs of the industry by some fixed amount M, i.e., $TR-TC=M$. The objective is now to maximize social welfare (W) subject to the constraint $TR-TC-M=0$. The necessary conditions for a maximum are found to be:

$$P-\frac{MC_1}{P}=\frac{\lambda}{(1-\lambda)}\,\frac{1}{E}$$

$$P-\frac{MC_2}{P}=\frac{\lambda}{(1-\lambda)}\,\frac{1}{E}$$

where $E=(P/X)(dX/dP)$ is the elasticity of demand for transportation, and λ is a multiplier reflecting the cost or reduction in welfare resulting from the presence of the break-even constraint.[9]

These conditions are identical to those derived by Baumol and Bradford and simply show that in this single commodity model when a profit constraint is present the optimal price should exceed marginal cost by an amount proportional to the inverse of the elasticity of demand. Thus, when the elasticity of demand is high price will exceed marginal cost by less than when the elasticity of demand is low. The conditions also imply that the quantities of commodity carried by each mode must be

[8] Let $C_1(X_1)$ = the long-run total cost function of mode 1
$C_2(X_2)$ = the long-run total cost function of mode 2
where X_1 = amount of commodity carried by mode 1
and X_2 = amount of commodity carried by mode 2

The objective is to maximize

$$W=\int_0^X G(X)dX-C_1(X_1)-C_2(X_2);$$
$$X=X_1+X_2$$

The necessary conditions for a maximum are

$$\frac{\partial W}{\partial X_1}=P-\frac{\partial C_1}{\partial X_1}=0$$
$$\frac{\partial W}{\partial X_2}=P-\frac{\partial C_2}{\partial X_2}=0$$

Hence $P=MC_1=MC_2$

[9] The objective is to maximize $W=\int_0^X G(X)dX-C_1(X_1)-C_2(X_2)$ subject to: $TR-TC-M=PX-C_1(X_1)-C_2(X_2)-M=0$

The maximization calculation yields

$$P-MC_1=\lambda[MR-MC_1]$$
$$P-MC_2=\lambda[MR-MC_2]$$

where MR (marginal revenue) $=P+X(dP/dX)$ substitution of $E=(P/X)(dX/dP)$ into these expressions yields the necessary conditions stated in the text.

such that the marginal costs of each mode are equal.

III. Conclusions

Consider first the problem of cost. From the models presented above it is clear that where a fixed amount of transportation service is to be allocated between two modes, it is total cost and not marginal cost which must be the basis of rational allocation. Moreover any change in total demand means that the optimal share of commodity to be carried by each mode will change, since a change in demand involves a whole new solution to the cost-minimization problem. It is possible that small changes in demand could be dealt with by comparing marginal costs and allocating the extra commodity to the mode with the lowest marginal cost at the point of the previous solution. Also it would be possible to discover a misallocation of resources if differences were observed in marginal costs. However, if there were substantial changes in demand a simple comparison of marginal costs would not lead to the correct solution.

The question of inherent advantage should be discussed in the light of these conclusions. If, by preserving the inherent advantage of each mode, Congress is in fact attempting to ensure that transportation services are provided at minimum cost, then it is the cost structure of the industry as a whole which must be considered and not the cost curves of each mode in isolation. The question of which mode should carry the traffic cannot be answered in simple terms. It makes no sense to suggest that one mode has an inherent advantage and should therefore carry the traffic unless this is the solution obtained from the cost minimization problem *at the specified level of demand*.

It should be noted here that the cost evidence typically used by the *ICC* in making decisions in contested rate cases consists of a single cost figure for each mode (usually fully distributed costs, sometimes marginal cost) calculated at the current output level.[10] The models make it clear that at least some evidence of how costs change with respect to the quantity of transportation provided would be a step towards better decision making.

In Model 2 a downward-sloping demand schedule for transportation was introduced. The maximization of social welfare results in a single optimal price for transportation to be charged by both modes and equal to the marginal cost of each mode. As before, information about total costs is needed to find the optimal solution, and, as before, any change in demand will change the optimal division of commodities between the modes and the optimal price.

Consider now the second best solution to the welfare-maximization problem in which each mode must at least break even, or make a positive profit. Congress has traditionally been concerned with the need to preserve competitive practices in the transportation industry. Both the 1940 Transportation Act and also Section 15 a(3) stress the goal of efficiency and the need to preserve competition to ensure the achievement of the efficiency objective. However, it is clear from recent *ICC* policy that the interpretation of Congressional intent has resulted in an attempt to protect competitors from the inevitable effects of competition, and the refusal to allow price reductions, other-

[10] For example, in the Ingot Molds case the barges declared their fully distributed cost to be \$5.1959 per gross ton. The railroads declared their out-of-pocket cost to be \$4.689 per gross ton and presented several different calculations of fully distributed cost ranging from \$7.80 per gross ton to \$6.613 per gross ton. It is not my intention to comment here on the usefulness of fully distributed cost as a cost measure, merely to point out that unless long-run average cost is constant for every level of output, a single cost figure measured at the current output level is an insufficient guide to the shape of the total cost function.

wise justifiable on efficiency grounds, which threaten at least the profits and possibly the existence of a competing mode. Since the desire to protect competitors often conflicts with the objective of achieving efficiency through competition, a decision by Congress to preserve the existence of competitors cannot be explained on rational economic grounds alone, and must therefore be accepted as part of some social preference function which is revealed in the actions of Congress and the *ICC*. While the economist may not be expected to explain the social preferences behind Congressional action, he can clarify the cost society incurs by attempting to preserve the existence of all competing modes.

In Model 3, the value of the multiplier λ can be interpreted in the following way. Suppose that the initial situation is an ideal one in which all prices in the economy are set equal to marginal costs. The decreasing cost mode is therefore making a loss but is being subsidized by the government using a system of lump sum taxes and transfers which does not distort marginal relationships. When the profit constraint ($TR-TC=M$) is imposed on the industry the price of transportation rises and the quantity provided decreases. The multiplier λ is the dollar value which buyers of transportation would put on a one dollar reduction in the size of M. It is the price which transportation consumers would pay to be able to return to the initial situation. In this sense λ measures the social welfare loss incurred by insisting that the industry as a whole make a profit. Presumably, a change in the profit level required for either or both modes will affect the price and quantity carried by both modes. In particular, an increase in the profit constraint for the increasing cost mode would increase the quasi-optimal price and decrease the quantity carried by all modes (since the demand curve is downward sloping). Moreover it would also tend to reduce the share of traffic carried by the decreasing cost mode, since, when the quantity of traffic to be carried is large, a greater proportion will be carried by the decreasing cost mode, but when the quantity is small the increasing cost mode will carry most of it.

Note that if the initial situation is one in which the existence of decreasing costs has led to subsidization or monopoly pricing which distorts the allocation of resources away from the Pareto optimal allocation then social welfare losses are already being incurred. In this case the introduction of a break-even constraint on the decreasing cost industry might reduce welfare losses. Certainly the conditions for constrained welfare maximization derived by Baumol and Bradford yield a price which is less distorting than that which would be charged by a profit-maximizing monopolist.

Appendix

Formally, the cost-minimization problem can be expressed as follows:

Let $C_1(X_1)=$ the long-run total cost function of mode 1

Let $C_2(X_2)=$ the long-run total cost function of mode 2

where $X_1=$ amount of commodity carried by mode 1

and $X_2=$ amount of commodity carried by mode 2

Then the objective is to minimize

$$C_1(X_1)+C_2(X_2) \tag{1}$$

subject to: $X_1+X_2=\overline{X}$

Let

$$\begin{aligned} f(X_1,\overline{X}) &= C_1(X_1)+C_2(X_2) \\ &= C_1(X_1)+C_2(\overline{X}-X_1) \end{aligned}$$

Now $f(X_1,\overline{X})$ can be expressed as

$$(2) \quad f(X_1, \overline{X}) = \int_0^{X_1} MC_1(\mu)d\mu + \int_0^{\overline{X}-X_1} MC_2(\mu)d\mu$$

Given $\overline{X}$, the conditions for finding that value of X_1, $(\hat{X}_1)$, which minimizes $f(X_1, \overline{X})$ can be derived as follows (note that these conditions will only indicate a *local* minimum).

There are three possible types of solution:

1. If $\hat{X}_1=0$, then we must have

$$(3) \quad f'(\hat{X}_1, \overline{X}) = MC_1(\hat{X}_1) - MC_2(\overline{X} - \hat{X}_1) \geq 0$$

where

$$f'(\hat{X}_1, \overline{X}) = \frac{df}{dX_1}$$

but if $\hat{X}_1=0$ and $f'(\hat{X}_1)=0$ then we must have

$$(4) \quad f''(\hat{X}_1, \overline{X}) = \frac{dMC_1}{dX_1}(\hat{X}_1) + \frac{dMC_2}{dX_1}(\overline{X} - \hat{X}_1) \geq 0$$

where

$$f''(\hat{X}_1, \overline{X}) = \frac{d^2f}{dX_1^2}$$

2. If $0<\hat{X}_1<\overline{X}$, then we must have *both*

$$f'(\hat{X}_1, \overline{X}) = 0 \quad and \quad f''(\hat{X}_1, \overline{X}) \geq 0$$

3. If $\hat{X}_1=\overline{X}$, then we must have $f'(\hat{X}_1, \overline{X}) \leq 0$. If $\hat{X}_1=\overline{X}$ *and* $f'(\hat{X}_1, \overline{X})=0$, then we must have $f''(\hat{X}_1, \overline{X}) \geq 0$.

To illustrate the meaning of these conditions consider the case shown in Figure 3.

Suppose $\overline{X}=\overline{X}'$ in Figure 3. Then it is true that $0<\hat{X}_1<\overline{X}$; in other words, both X_1 and X_2 are positive and both modes are in operation.

From point 2 above the following conditions must be fulfilled:

$$(5) \quad f'(\hat{X}_1, \overline{X}) = MC_1(\hat{X}_1) - MC_2(\overline{X} - \hat{X}_1) = 0$$

and

$$(6) \quad f''(\hat{X}_1, \overline{X}) = \frac{dMC_1}{dX_1}(\hat{X}_1) + \frac{dMC_2}{dX_1}(\overline{X} - \hat{X}_1) \geq 0$$

Condition (5) is nothing more than the equal marginal cost condition. For condition (6) to hold we must have

$$\frac{dMC_1}{dX_1}(\hat{X}_1) \geq \frac{dMC_2}{dX_1}(\overline{X} - \hat{X}_1)$$

since $dMC_2/dX_1(\overline{X}-\hat{X}_1)$ is negative. In other words, the marginal cost curve of mode 1 must be increasing at a faster rate than the marginal cost curve of mode 2 is decreasing; the summed marginal cost curve is forward sloping as shown in Figure 3.

Now consider the case shown in Figure 4. Suppose $\overline{X}<\overline{X}'$ in Figure 4. Then it is true that $\hat{X}_1=\overline{X}$, therefore we must have $f'(\hat{X}_1, \overline{X}) \leq 0$ (from point 3 above), i.e.,

$$MC_1(\hat{X}_1) \leq MC_2(\overline{X} - \hat{X}_1)$$

As Figure 4 is drawn there is no internal solution for $\hat{X}_1$. Therefore *either* $\hat{X}_1=0$, *or* $\hat{X}_1=\overline{X}$, and it will *not* be the case that $f''(\hat{X}_1, \overline{X}) \geq 0$.

Further examination of Figures 1 and 2 will show that these cases can also be interpreted using the above conditions for a local minimum.

Optimal Restrictions on Foreign Trade and Investment: Note

By RAVEENDRA N. BATRA*

Optimal policy in the presence of international trade and investment, which has been previously analyzed by Murray Kemp and Ronald Jones (1967) in the context of a two-factor, two-good general equilibrium model, constitutes the subject of analysis in a recent article in this *Review* by Franz Gehrels. Gehrels' framework, which postulates a three-factor, two-good economy, differs from that of Kemp and Jones in format but not in substance. Nevertheless, Gehrels has made an important contribution by providing a more complete discussion of "partial" optimization and by deriving optimal tariffs and taxes in the presence of the interindustry wage differential that characterizes factor markets in the underdeveloped countries.

The objective of this note is to show that Gehrels' optimal policy in the presence of the wage differential is incomplete and that his modification of the optimum tariff formula is not always valid.

The assumptions and notations used in this note are the same as those introduced by Gehrels. The problem is to maximize the social utility function

$$(1) \qquad U = U(C_1, C_2) = U(Y_1 - X_1,\ Y_2 - X_2)$$

subject to the production constraint

$$(2) \qquad \phi(Y_1, Y_2, F) = 0$$

and the balance-of-payments constraint

$$(3) \qquad X_1 + X_2\pi + F\rho = 0$$

where C_1 and C_2 are consumption of good 1 and good 2, Y_1 and Y_2 are their outputs, and X_1 and X_2 are their exports or imports depending on whether X_i is positive or negative; F is the amount of foreign investment which is positive if the country in question is a net creditor and negative if it is a net debtor; ρ is the foreign rate of interest; and π is the international terms of trade with the first commodity serving as numeraire.

In conformity with the reality in several developing countries, Gehrels assumes that the country in question is a net debtor, so that $F<0$, imports X_2, so that $X_2<0$, and that the wage differential is paid by the import-competing good, Y_2. Two effects follow immediately from the presence of the differential. First, the transformation curve shifts toward the origin, and second, the marginal rate of transformation no longer reflects the commodity-price ratio, that is,

$$-\frac{\partial Y_1}{\partial Y_2} = bp$$

where $b>1$, indicating that the production costs in Y_2 exceed its social opportunity cost. Let t stand for the rate of tariff; then $p=\pi(1+t)$. The optimum tariff formula derived by Gehrels here is given by his equation (26) which furnishes

$$t = \frac{p-\pi}{\pi} = \frac{X_2}{\pi}\cdot\frac{\partial\pi}{\partial X_2} + \frac{F}{\pi}\cdot\frac{\partial\rho}{\partial X_2} - (b-1)\frac{\partial Y_1}{\partial X_2}$$

As Gehrels shows, $\partial\pi/\partial X_2$ and $\partial\rho/\partial X_2$ are both negative and with X_2 and F also negative, each of the first two terms in this formula is positive. At the start of his paper, he contends that $\partial Y_1/\partial X_2<0$ and $\partial Y_2/\partial X_2>0$, irrespective of the sign of X_i. With X_2 equaling the import, this must be taken to mean that a rise in the relative price of the second good leads to a decline in Y_1 (so that $dY_1<0$) and a decline in the demand for imports (so that with $X_2<0$, $dX_2>0$), which eventually

* Professor of economics, Southern Methodist University.

implies that $(\partial Y_1/\partial X_2)<0$. With $(b-1)>0$, all this leads us to Gehrels' result that the optimal tariff is not only positive, but the existence of the differential also causes a rise in the import duty, if welfare is to be maximized.

However, in the presence of the wage differential, the sign of $(\partial Y_1/\partial X_2)$ is no longer certain. Working with a two-factor, two-good model, Jagdish Bhagwati and T. N. Srinivasan, Jones (1971), and Batra and Prasanta Pattanaik among others have shown that the output of a commodity may actually decline in response to a rise in its relative price when factor markets are distorted by the existence of a wage differential. Furthermore, this result is independent of the shape of the transformation curve. There is no reason why this result should not continue to hold in the three-factor, two-good model, the one used by Gehrels. Thus $\partial Y_1/\partial X_2$ may be positive or negative. If $\partial Y_1/\partial X_2$ is positive, we reach the surprising conclusion that the optimal tariff in the presence of the distortion will be less than what it would be in its absence.

Of greater interest is the fact that the nature of the price-output response in the presence of the differential makes no difference to the optimal tax (or subsidy) on foreign investment. This becomes clear from an examination of the terms contained in Gehrels' equation (32), where[1]

$$\frac{r-\rho}{\rho}=\frac{X_2}{\rho}\frac{\partial\pi}{\partial F}+\frac{F}{\rho}\frac{\partial\rho}{\partial F}+\frac{p}{\rho}\cdot\frac{(b-1)}{b}\frac{\partial Y_2}{\partial F}$$

The sign of $\partial\rho/\partial F$ depends on conditions in the foreign country and if the factor markets there are perfect, $\partial\rho/\partial F$ is unmodified. The signs of $\partial\pi/\partial F$ and $\partial Y_2/\partial F$ are governed by the relationship between factor endowments and the commodity outputs and this relationship is not affected by the existence of the differential.[2] Thus, none of the terms in the optimal tax formula depends on the price-output response, so that Gehrels' results in this case are unscathed.

In the presence of distorted factor markets, a distinction must be introduced between the second best and the first best optimal policy. The optimal tariffs and taxes derived by Gehrels will only lead to the second best optimum, for the inefficiency caused by the existence of the differential in shrinking the transformation curve toward the origin will still remain. The first best policy, the policy which will truly maximize welfare, consists of the grant of factor tax-cum subsidy which has the effect of eliminating the wage differential to the domestic producers of the two outputs (but not to the suppliers of capital or labor), plus the optimal tariff and tax to capture the advantage of the country's monopoly power in international trade and investment. This policy will have the effect of equating b to unity and thus eliminating the last terms from the optimal tariff and tax formulae. At the same time, the economy's production point will move back to somewhere on the undistorted transformation curve.

Residential Choice and Air Pollution: A General Equilibrium Model

By EUGENE P. SESKIN*

Pigou's parable of the smoke belching factory imposing an externality on the neighboring laundry has elicited more controversy than one could have expected from such a simple situation. Ronald Coase claimed that the Pigouvian solution of taxes and subsidies was demonstrably inefficient while William Baumol recently defended Pigou by presenting a situation in which a tax placed upon the factory (without taxation or compensation to the laundry) optimizes resource allocation under pure competition.

What if the externality affects the factory itself? Suppose the smoke reduces the work efficiency of employees and causes ill health. It might be conjectured that nothing new is gained by adding the wrinkle of poisonous air which sickens factory workers, since the factory both generates the smoke and is affected by it. By analogy, a "smoke city" where everyone works in factories generating air pollution (which affects only the city) might be deemed consistent with Pareto optimality, presuming the factories compensate individuals for the air pollution with higher wages.[1] Similarly, recent policy discussions have advocated "exporting" air pollution by importing pollution-producing goods. Little concern has been given to the welfare implications since the "republic of smoke" would be experiencing the profit as well as the pollution from production. There are even proponents of the view that some regions of the United States ought to be kept quite clean, while others are allowed to become highly polluted. Their reasoning is that if workers are mobile and acting in a competitive market, they will demand and receive higher wages for living in the polluted locality and the resulting situation will be Pareto optimal.

This paper will show these arguments to be fallacious. For externalities such as air pollution, it is precisely the assumptions of competition and mobility which destroy Pareto optimality. Restoration of efficiency can occur only through outside intervention designed to alter factor prices.

I. The Model[2]

Suppose there exists an economy comprised of two cities: one producing a good which does not cause air pollution (we shall name it bread and refer to the area as bread city); the other manufacturing a commodity which produces air pollution as a by-product (we shall name it steel and refer to the region as steel city). Further, we assume a population of individuals (normalized so that the total population is equal to 1)[3] allocated between the two cities with θ living and working in steel city and $1-\theta$ inhabiting bread city.[4] The problem is determining whether with free movement between the cities (no transportation or moving costs), the wage rates will adjust so that the total population will allocate itself in a Pareto optimal fashion.[5]

* The Urban Institute. I am deeply indebted to Nancy M. Gordon, Lester B. Lave, Robert E. Lucas, Jr., and Thomas E. Morton for helpful comments and suggestions. I am especially indebted to Herbert A. Simon, who is co-author of the Appendix section.

[1] This assumes competition and mobility among workers.

[2] The basic framework of this model is similar to the transportation parables of Robert Strotz.

[3] Note, in checking the units of the various expressions we will derive, this normalization results in an occasional implicit multiplicative factor of 1 which has the units of population.

[4] An alternative interpretation is to regard the total population as allocating θ percent of their time to living and working in steel city and $1-\theta$ percent of their time to living and working in bread city.

[5] In our model the particular Pareto optimum will correspond to the maximum of a linear social welfare function, see below.

A. *The Utility Function*

Each individual in the population is assumed to have an identical utility function.[6] Since conditions in the two cities differ (air pollution is not present in bread city), we shall represent the utility for a resident of steel city as shown in equation (1):

$$u^s = u(s^s, b^s, a) \tag{1}$$

where s^s is the steel consumption per capita in steel city, b^s is the per capita bread consumption in steel city, and a is the amount of air pollution to which an individual in steel city is subjected.[7] Similarly, utility for each bread city resident is:

$$u^b = u(s^b, b^b, 0) \tag{2}$$

The amount of bread and steel consumed by the individual enters each utility function positively, u_1 and $u_2 > 0$ (where the subscripts refer to the partial derivatives with respect to that argument). The partial derivative with respect to a, u_3, is negative, indicating that air pollution is a "bad."

B. *Production Possibilities*

The only resource available for production of bread and steel is labor. Thus, there is a fixed aggregate quantity, 1 (total population), of this homogeneous productive resource available to the economy. The distribution of population will uniquely determine the production of bread and steel. Both commodities are produced in perfectly competitive industries under constant returns with each individual producing one unit of the relevant commodity, i.e., each bread worker produces one unit of bread.[8] Total bread output is equal to the population of bread city, $1-\theta$, and is distributed such that θb^s represents the population of steel city multiplied by the bread consumption per capita for steel city residents and $(1-\theta)b^b$ is the population of bread city multiplied by the bread consumption per capita for bread city residents. An analogous interpretation applies to steel production. Thus, the production constraints in per capita terms are:[9]

$$\theta b^s + (1-\theta)b^b = 1-\theta \text{ (bread)} \tag{3}$$

$$\theta s^s + (1-\theta)s^b = \theta \text{ (steel)} \tag{4}$$

For simplicity we assume that each steel worker not only produces a unit of steel, but also produces a unit of pollution in the making of steel ($a \equiv \theta$); henceforth θ will replace a as the value of the third argument in the utility function for the people of steel city. Thus, the number of units of pollution is identical to the number of units of steel, which in turn is equal to the population of steel city.

II. Individual Utility Maximization

Let each individual be paid the value of his marginal product, i.e., the steel worker's income is $1 \text{x} p^s$ (one unit multiplied by the price of steel) and the bread worker's income is $1 \text{x} p^b$ (one unit multiplied by the price of bread). The consumer is then faced with maximizing his utility subject to his budget constraint. We formulate the respective Lagrangeans:

$$\begin{aligned} &u(s^s, b^s, \theta) \\ &\quad + K^s(p^s - p^s s^s - p^b b^s) \qquad \text{(steel city)} \end{aligned} \tag{5}$$

$$\begin{aligned} &u(s^b, b^b, 0) \\ &\quad + K^b(p^b - p^s s^b - p^b b^b) \qquad \text{(bread city)} \end{aligned} \tag{6}$$

where K^s and K^b are Lagrange multipliers. We then take the partial derivatives with respect to steel and bread consumption, the variables at the consumer's disposal:[10]

$$u_1^s - K^s p^s = 0 \tag{7}$$

[6] Any two individuals consuming the same bundle of goods (including air pollution) would derive equal levels of satisfaction.

[7] There is no superscript on a since air pollution is not present in bread city. Further, it is assumed that air pollution is uniform throughout steel city with each individual consuming the same amount; it is a public "bad."

[8] One can think of individuals owning shares in the bread and steel factories.

[9] Note, the equalities in equations (3) and (4) imply full utilization of the goods.

[10] We assume the individual in steel city regards θ as a parameter, i.e., the level of pollution is independent of his steel consumption.

$$u_2^s - K^s p^b = 0 \tag{8}$$

$$u_1^b - K^b p^s = 0 \tag{9}$$

$$u_2^b - K^b p^b = 0 \tag{10}$$

Dividing (7) by (8) and (9) by (10) we obtain:[11]

$$\frac{\bar{u}_1^s}{\bar{u}_2^s} = \frac{\bar{u}_1^b}{\bar{u}_2^b} = \frac{\bar{p}^s}{\bar{p}^b} = \frac{1 - \bar{b}^b}{\bar{s}^b} \tag{11}$$

This, of course, is the familiar fact that the ratio of the marginal utilities from steel and bread must equal the ratio of the respective prices at the maximum. Furthermore, we require that θ be such that the utilities in the two cities are equal to each other, i.e., $u(s^s, b^s, \theta) = u(s^b, b^b, 0)$. If this were not the case, people would move from one city to another. This would violate our notion of equilibrium since total welfare could be increased by such migration. We denote the solution values of our equilibrium conditions by $\bar{s}^s$, $\bar{b}^s$, $\bar{\theta}$, $\bar{s}^b$, and $\bar{b}^b$.

III. Conditions for a Pareto Optimum

Pareto optimality will be achieved if each consumer's utility is a maximum given the utility levels of all other consumers. Following the approach set forth by Strotz, we shall alternatively interpret the problem so as to maximize the linear social welfare function,

$$\sum_s u(s^s, b^s, \theta) + \sum_b u(s^b, b^b, \theta) = \theta u(s^s, b^s, \theta) + (1 - \theta) u(s^b, b^b, 0)$$

given the available resources (total labor supply) and the production alternatives open to society (equations (3) and (4)). The equality comes from the fact that all individuals are identical, i.e., the welfare weights are assumed to be unity. Mathematically we set up the Lagrangean:

$$\begin{aligned}\theta u(s^s, b^s, \theta) &+ (1 - \theta) u(s^b, b^b, 0) \\ &+ \mu[\theta b^s + (1 - \theta) b^b - (1 - \theta)] \\ &+ \gamma[\theta s^s + (1 - \theta) s^b - \theta] \\ &+ \delta[u(s^s, b^s, \theta) - u(s^b, b^b, 0)]\end{aligned} \tag{12}$$

where μ, γ, and δ are Lagrange multipliers insuring that the constraints are not violated. Note the last constraint is derived from our requirement that the utilities in the two cities be equal to each other.

Differentiating (12) with respect to s^s, b^s, s^b, b^b, and θ, respectively:

$$u_1^s(\theta + \delta) + \gamma\theta = 0 \tag{13}$$

$$u_2^s(\theta + \delta) + \mu\theta = 0 \tag{14}$$

$$u_1^b(\theta - \delta) + \gamma(1 - \theta) = 0 \tag{15}$$

$$u_2^b(\theta - \delta) + \mu(1 - \theta) = 0 \tag{16}$$

$$\begin{aligned}u(s^s, b^s, \theta) - u(s^b, b^b, 0) \\ + \theta u_3^s + \mu(b^s - b^b + 1) \\ + \gamma(s^s - s^b - 1) + \delta u_3^s = 0\end{aligned} \tag{17}$$

Dividing (13) by (14) and (15) by (16) we obtain:

$$\frac{u_1^s}{u_2^s} = \frac{u_1^b}{u_2^b} = \frac{\gamma}{\mu} \tag{18}$$

Rearranging (17), using (14), the production constraints (equations (3) and (4)), and the requirement that the utilities in the two cities are equal, we find:[12]

$$\frac{\gamma}{\mu} = \frac{1 - b^b}{s^b} = \frac{u_3^s \theta^2}{u_2^s s^b} \tag{19}$$

Equating (18) and (19) we derive a necessary condition for an optimum.[13]

[11] The last equality is derived from the income constraint for bread city residents in equation (6). The partial derivatives of the steel city and bread city utility functions are evaluated at ($\bar{s}^s$, $\bar{b}^s$, $\bar{\theta}$) and ($\bar{s}^b$, $\bar{b}^b$), respectively.

[12] In this expression, s^b has the units of steel, not steel per person. See fn. 3.

[13] This is the price ratio which will induce "optimal" behavior from the consumers in the two cities. A hat over a variable denotes the value attained at the optimum. In this case, the derivatives of the steel-city and bread-city utility functions are evaluated at ($\hat{s}^s$, $\hat{b}^s$, $\hat{\theta}$) and ($\hat{s}^b$, $\hat{b}^b$, 0), respectively.

$$\frac{\hat{u}_1^s}{\hat{u}_2^s} = \frac{\hat{u}_1^b}{\hat{u}_2^b} = \frac{1 - \hat{b}^b}{\hat{s}^b} - \frac{\hat{u}_3^s \hat{\theta}^2}{\hat{u}_2^s \hat{s}^b} = \frac{\hat{p}^s}{\hat{p}^b} \tag{20}$$

IV. Individual Maximization and Pareto Optimality

We now ask whether individual utility maximization, subject to fixed unit prices common to all individuals, will lead to a Pareto optimum.[14] To do this it is sufficient to compare $\bar{\theta}$ with $\hat{\theta}$. If they are not equal, production will be incorrect, i.e., too much or too little steel will be produced. More precisely, we shall prove that $\bar{\theta} > \hat{\theta}$, i.e., optimality requires a redistribution of population from steel city to bread city with less steel production (and less pollution).

First, we examine the expenditures of a bread city resident in the two situations in terms of bread units:

$$E_b^b = b^b + \frac{p^s}{p^b} s^b \tag{21}$$

where E_b^b represents the number of units of bread a resident could buy if no steel was bought.

Substituting the price ratio corresponding to individual maximization (using equation (11)) into equation (21) we obtain:

$$\bar{E}_b^b = 1 \tag{22}$$

Hence, the income of bread workers (in this case, the price of bread) is equal to unity.

Similarly, we use the price ratio at an optimum (from equation (20)) and substitute it into equation (21) and find:

$$\hat{E}_b^b = 1 - \frac{\hat{u}_3^s \hat{\theta}^2}{\hat{u}_2^s} \tag{23}$$

Remembering that $u_3 < 0$, we see optimality requires that the income in units of bread for bread workers exceed unity.[15]

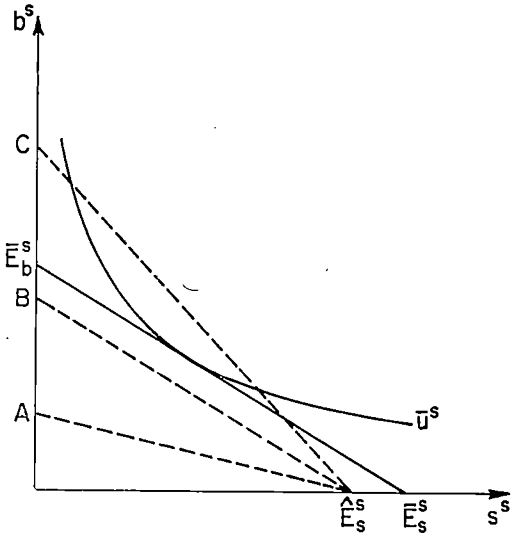

FIGURE 1

Figure 1 illustrates the situation for a representative individual of steel city. The axes are labeled his consumption of bread and steel and an indifference curve is drawn at the equilibrium point under individual maximization tangent to the equilibrium price ratio.[16] We have just stated (fn. 15) that under optimality the income of steel city residents in terms of steel units falls, hence, we can arbitrarily pick a point to the left of $\bar{E}_s^s$ and label it $\hat{E}_s^s$. We then graph all three possibilities for the change in relative prices from individual maximization to optimality: the price ratio can fall, $(A\hat{E}_s^s)$, remain constant, $(B\hat{E}_s^s)$, or increase, $(C\hat{E}_s^s)$. We know that the level of utility which the individual attains under optimality must be at least as high as his utility under individual maximization; hence if the price ratio either falls or remains constant, pollution (and steel production) must decrease.[17]

Thus, we will limit ourselves to the cases in which the price ratio might increase. From

[14] Note that the Pareto situation is a generalization of the case of individual utility maximization with the removal of the constraint that expenditures equal wage income. Therefore, by the Le Chatelier principle, the Pareto situation must be at least as good as individual maximization; if it differs it must be superior.

[15] Using the fact that $(1-b^b)/s^b = b^s/(1-s^s)$ and that $(1-b^b)/s^b - u_3^s\theta^2/u_2^s s^b = b^s/(1-s^s) - u_3^s\theta(1-\theta)/u_2^s(1-s^s)$ we can likewise show that $\bar{E}_s^s > \hat{E}_s^s$.

[16] The figure is only in the dimensions of bread and steel; hence, each indifference curve has a level of pollution, θ, associated with it.

[17] Mathematically, if $\hat{p}^s/\hat{p}^b \leq \bar{p}^s/\bar{p}^b$ then $\bar{\theta} > \hat{\theta}$ in order that $\hat{u}^s \geq \bar{u}^s$.

equations (11) and (20) this means we will be examining cases for which the following holds:

$$(24)\qquad \frac{\bar{u}_1^s}{\bar{u}_2^s} = \frac{\bar{u}_1^b}{\bar{u}_2^b} < \frac{\hat{u}_1^s}{\hat{u}_2^s} = \frac{\hat{u}_1^b}{\hat{u}_2^b}$$

Using (24), the production constraints (equations (3) and (4)), the fact that $\hat{u}^s = \hat{u}^s \geq \bar{u}^s = \bar{u}^b$, the assumption of diminishing marginal utility, and the neutrality of pollution,[18] we can enumerate the admissible changes in our variables:[19]

s^b	+	+	+	−	−	−	−	−	0	0	0
b^b	+	+	+	+	+	+	+	+	+	+	+
θ	−	−	−	−	−	−	−	−	−	−	−
s^s	−	−	−	0	−	−	−	+	−	−	−
b^s	0	+	−	+	0	+	−	+	0	+	−

We see the only possible changes involve a reduction in θ. Without some externally imposed adjustment, i.e., tax, the results from individual utility maximization will not adequately reflect the externality associated with steel production. Individuals moving to steel city will not take account of the extra pollution they subject all steel city residents to and the externality will not be completely internalized. Thus, there will be a misallocation of resources (labor) between the two cities.

[18] By neutrality, we mean that a change in the pollution level does not affect the relative marginal utility of bread and steel consumption.

[19] The table indicates the direction of change of the variable from individual maximization to optimality, e.g., s^b followed by a + means that $\hat{s}^b > \bar{s}^b$. For example, looking at the first column, we see that both s^b and b^b may increase so as to satisfy the relation in (24) pertaining to bread city, i.e., that the ratio of marginal utilities increases. At the same time, it is clear that this will mean that $\hat{u}^b \geq \bar{u}^b$ since more of both goods are being consumed. A consistent solution for steel city would involve a reduction in s^s with b^s remaining constant. This would necessitate a decrease in θ. θ could not increase or remain unchanged if both s^b and b^b rise and our relationships are satisfied. Similar arguments can be made for the other columns in the table.

V. The Tax

Comparing equations (22) and (23), we see that an income transfer from residents of steel city to residents of bread city must take place to attain optimality from individual maximization. The magnitude of this transfer (in terms of bread units) is given by:

$$(25)\qquad \tau = \hat{E}_b^b - \bar{E}_b^b = -\frac{\hat{u}_3^s \hat{\theta}^2}{\hat{u}_2^s} = -\frac{\hat{u}_3^s}{\hat{u}_2^s/\hat{\theta}}\,\hat{\theta} > 0$$

This quantity can be viewed as a tax on and subsidy to the factors of production.[20] Thus, steel producers are taxed for employing the "pollution-creating" input (steel labor), while bread producers are subsidized for utilizing the "pollution-free" input (bread labor). The resulting new demand curves for labor lead to an optimal reallocation of resources.

In our case, there is another interpretation to the assessment. The numerator of the tax collected from everyone in steel city (θ people) represents the marginal disutility per person (for all people) of a change in the pollution level and the denominator represents the marginal utility of bread per person in steel city. Hence, the ratio measures the disutility of pollution relative to the utility of bread for people in steel city. When multiplied by the population of steel city, this reflects the total amount of bread they should be willing to give up to decrease the level of pollution.

VI. A Numerical Example

This conclusion can be made clearer through the use of a numerical example. We shall derive the results for individual utility maximization and for a Pareto optimum utilizing the following Cobb-Douglas utility functions:[21]

$$(26)\qquad u^s = \bar{e}^{\theta}(s^s)^{1-\beta}(b^s)^{\beta} \quad \text{(steel city)}$$

$$0 < \beta < 1$$

$$(27)\qquad u^b = (s^b)^{1-\beta}(b^b)^{\beta} \quad \text{(bread city)}$$

[20] Alternatively, it can be looked upon as an inducement to the labor force to change their working patterns. See fn. 4.

[21] Note, for bread city, $\theta = 0$ and $\bar{e}^{\theta} = 1$ which results in (27).

We can now use these functions, together with the production constraints (equations (3) and (4)), the budget constraints (equations (5) and (6)), and the condition in equation (11) to solve a system of simultaneous equations for the unknowns $\bar{s}^s$, $\bar{s}^b$, $\bar{b}^s$, $\bar{b}^b$, and $\bar{P}$ in terms of β and θ:[22]

$$\bar{s}^s = 1 - \beta \tag{28}$$

$$\bar{s}^b = \frac{\beta\bar{\theta}}{1-\bar{\theta}} \tag{29}$$

$$\bar{b}^s = \frac{(1-\bar{\theta})(1-\beta)}{\bar{\theta}} \tag{30}$$

$$\bar{b}^b = \beta \tag{31}$$

$$\bar{P} = \frac{(1-\beta)(1-\bar{\theta})}{\beta\bar{\theta}} \tag{32}$$

Substituting these values into (26) and (27) and remembering that in equilibrium the utilities in the two cities must be equal we obtain:

$$e^{-\bar{\theta}}\left(\frac{1-\bar{\theta}}{\bar{\theta}}\right) = \frac{\beta}{1-\beta} \tag{33}$$

Letting $\beta=.38$, we can solve (28) through (33) for approximate numerical values of the variables. We find that steel consumption per capita in steel city ($\bar{s}^s$) is .62, steel consumption per capita in bread city ($\bar{s}^b$) is .38, bread consumption per capita in steel city ($\bar{b}^s$) is .62, and bread consumption per capita in bread city ($\bar{b}^b$) is .38. The relative price ratio ($\bar{P}$) is 1.63. The total population is equally distributed between the two cities ($\bar{\theta}=.50$).[23] Finally, the level of utility for each individual in society ($\bar{u}^s=\bar{u}^b$) is .38.

Now, we solve for the optimum values using the Cobb-Douglas utility functions and relation (20):

$$\hat{s}^s = \frac{1-\beta}{1+\hat{\theta}-\hat{\theta}^2} \tag{34}$$

$$\hat{s}^b = \frac{\hat{\theta}}{1-\hat{\theta}}\left(\frac{\beta+\hat{\theta}-\hat{\theta}^2}{1+\hat{\theta}-\hat{\theta}^2}\right) \tag{35}$$

$$\hat{b}^s = \frac{1-\hat{\theta}}{\hat{\theta}}\left(\frac{1-\beta}{1+\hat{\theta}-\hat{\theta}^2}\right) \tag{36}$$

$$\hat{b}^b = \frac{\beta+\hat{\theta}-\hat{\theta}^2}{1+\hat{\theta}-\hat{\theta}^2} \tag{37}$$

$$\hat{P} = \frac{(1-\beta)(1-\hat{\theta})}{\beta\hat{\theta}} \tag{38}$$

Again we substitute into the utility functions (equations (26) and (27)) and obtain:

$$e^{-\hat{\theta}}\left(\frac{1-\hat{\theta}}{\hat{\theta}}\right) = \frac{\beta}{1-\beta} + \frac{\hat{\theta}-\hat{\theta}^2}{1-\beta} \tag{39}$$

For $\beta=.38$, we solve (34) through (39) for the numerical values of the unknowns. In this case, steel consumption per capita in steel city ($\hat{s}^s$) is .50, steel consumption per capita in bread city ($\hat{s}^b$) is .33, bread consumption per capita in steel city ($\hat{b}^s$) is .75, and bread consumption per capita in bread city ($\hat{b}^b$) is .50. The relative price ratio ($\hat{P}$) is 2.45. Less of the total population now resides in steel city ($\hat{\theta}=.40$); hence, there is less steel production and less pollution. The level of utility for each individual ($\hat{u}^s=\hat{u}^b$) has now increased to .39. The tax (τ) imposed on steel city residents and transferred to each bread city inhabitant is .32.

VII. Discussion

We have posed a simple market situation in which an externality (air pollution) arises as an explicit joint product in the manufacture of a "normal" good. People engaged in the production of the good are subjected to the externality, but are free to move to another pollution-free environment and produce a different good.[24] We have shown that

[22] Since we are only concerned with relative prices, we define $P=p^s/p^b$. Note, too, that initially we are specifying a given distribution of population θ (and; hence, income). We will then search over θ so as to equate the individual utilities in the two cities.

[23] This, of course, is also the level of pollultion in steel city.

[24] Our model has dealt with the polar case of completely separate production locations. In this way, we allowed the market maximum freedom in coping with the problem; it was unable to do so in an optimal manner. Permitting bread production to take place in steel city would further aggravate the situation.

the market fails to allocate optimally the resources (population) without outside intervention. In particular, a tax on steel city residents or a subsidy to bread city residents is needed. If this activity is to be neutral with respect to distributional effects, there must be both a tax on steel city residents *and* a subsidy to bread city residents.

The essential element in the model which causes the market to fail is the fact that the externality takes the form of a pure public good (or, more precisely, a "pure public bad"). Allowing some people the choice of consuming more goods and subjecting themselves to more pollution does not lead to a Pareto optimum. The final person moving to steel city does not take account of the additional pollution he inflicts upon *all* steel city residents.

This result is of interest when one considers suggestions that we allow some cities to become the sewers for American production or that we export our pollution by importing pollution-producing goods. Clearly, these solutions are nonoptimal for society as a whole. Apparently, sewer city would be too polluted for Pareto optimality.

APPENDIX[25]

The nonoptimality theorem was proved under the rather strong assumptions that all individuals possessed identical cardinal utility functions. For it will be recalled that the original Pareto optimality conditions were derived by summing the individual utility functions. Here we allow each individual to possess his own differentiable utility function defined only up to a smooth monotonic transformation. Again, we assume positive marginal utilities for bread and steel, and negative marginal utilities for pollution. Moreover, we will use only the signs, not the marginal utilities in our derivation, and these signs are invariant under monotonic transformations of the functions. Hence, our results do not depend upon the cardinal scales of the utility functions, and we can regard these functions as defined ordinally.

Let each individual, i, have a differentiable utility function:

$$u^i = u^i(s^i, b^i, a^i) \tag{A1}$$

Again,

(A2) $a^i = 0$ for residents of bread city ($i \in B$)

(A3) $a^i = \theta$ for residents of steel city ($i \in S$)

Each person is constrained to spend no more than his income, which is equal to the value of his product plus (minus) his subsidy (assessment):[26]

$$p^i - p^s s^i - b^i + e^i = 0 \tag{A4}$$

where $p^i = 1$ for $i \in B$; $p^i = p^s$ for $i \in S$; and e^i is the subsidy (assessment) of the ith individual.[27]

Necessary conditions for competitive equilibrium again imply:

$$\frac{u_1^i}{u_2^i} = p^s \qquad \text{for all } i \tag{A5}$$

Now assume that some individuals are moved from steel city to bread city, so that there is a decrease, $d\theta$, in the population of the former city and in the production of steel, and a corresponding increase in the population of the latter city and in the production of bread. As a result of the decrease in steel production there is an increase, dp^s, in the relative price of steel.[28] We now calculate the consequent changes in utility:

$$du^i = u_1^i ds^i + u_2^i db^i + u_3^i da^i \tag{A6}$$

where $da^i = 0$ for $i \in B$, and $da^i = d\theta$ for $i \in S$.

From (A4), the derivative of the budget constraint with no subsidy or assessment is:

$$dp^i - p^s ds^i - s^i dp^s - db^i = 0 \tag{A7}$$

[25] Herbert A. Simon is coauthor of the Appendix.

[26] We assume that the government may assess (subsidize) any member of the population, and that the assessments (subsidies) may be different for different persons.

[27] Note, for simplification, we take the price of bread as numeraire, while the price of steel (per unit of bread) is p_s.

[28] We assume that a decrease in the production of steel and an increase in the production of bread always causes an increase in the price of steel relative to the price of bread. This condition is stated independently of the utility functions.

Using (A5) and (A7), we can rewrite (A6) as:

$$\text{(A8)} \quad \frac{du^i}{u_2^i} = dp^i - s^i dp^s + \left(\frac{u_3^i}{u_2^i}\right) da^i$$

or, more explicitly, for B and S separately:

$$\text{(A9)} \quad \frac{du^i}{u_2^i} = -s^i dp^s \qquad (i \in B)$$

$$\text{(A10)} \quad \frac{du^i}{u_2^i} = (1-s^i)dp^s + \left(\frac{u_3^i}{u_2^i}\right) d\theta \qquad (i \in S)$$

Since $dp^s > 0$ and $s^i > 0$, we see from (A9) that the population shift has lowered the utility of all residents of bread city. Since $s^i < 1$, $u_3^i < 0$, $u_2^i > 0$ and $d\theta < 0$, we see from (A10) that the population shift has increased the utility of all residents of steel city. Moreover, since the dimensionality of the terms in (A9) and (A10) is "loaves," we can determine immediately how large a subsidy or assessment, in the same units, would restore utilities to their previous levels.

We now give a subsidy to or impose an assessment on each person of such magnitude that his utility will be at least equal to its initial level.[29] If this scheme is to be feasible then the sum of the assessments must be equal to or greater than the sum of the subsidies (the government cannot redistribute more than it collects).

We wish to show that:

$$\text{(A11)} \quad \sum_U e^i = \sum_B e^i + \sum_S e^i < 0$$

[29] The quantities, e^i, are simply calculated by replacing the term on the left of (A8) (or equivalently (A9) and (A10)) by $-e^i$ (the minus sign so that the subsidy or assessment will be of opposite sign to the change in utility).

Using (A9) and (A10), with the proper substitutions (fn. 29), and reversing signs on both sides of the equations, we obtain:

$$\text{(A12)} \quad \sum_B e^i = dp^s \sum_B s^i$$

$$\text{(A13)} \quad \sum_S e^i = -\theta dp^s + dp^s \sum_S s^i - d\theta \sum_S \frac{u_3^i}{u_2^i}$$

(recalling that S contains θ persons).

Now, summing (A12) and (A13):

$$\text{(A14)} \quad \sum_U e^i = -d\theta \sum_S \frac{u_3^i}{u_2^i} < 0$$

(recalling that $\sum_B s^i + \sum_S s^i = \sum_U s^i = \theta$).

Thus, with this system of subsidies and assessments, which leaves all utilities unchanged from their initial levels, the government is left with a surplus which it can distribute among all persons so that all utilities will be higher than in the initial state.[30]

[30] Note, the surplus is exactly equal to the market value (i.e., bread equivalent) of the benefits obtained by residents of steel city from the lower pollution resulting from the reduction in population and steel production. The higher costs of steel to residents of bread city can be exactly compensated by assessing the higher cash incomes of residents of steel city.

Expectations and the Labor Supply

By CHARLES L. HEDRICK*

The long-run and short-run dynamics of the supply of national output are a key to macro-economic behavior. These dynamics form the basis of the "natural rate" analysis of Milton Friedman and others. And the key to the dynamics of the total supply is that of the labor supply. It would be an exaggeration to claim that capital supply and the behavior of firms is irrelevant to macroeconomics. But output can be viewed as the product of a cyclical employment variable with a more or less uniformly increasing productivity. Thus it is clear that the properties of the total supply are highly dependent upon those of the labor supply. The purpose of this paper is to explore the dynamics of the labor supply, with particular emphasis on the effect of expectations models. In the process a regression that Robert Lucas and Leonard Rapping used to explain the labor supply is replicated with more recent data. Although further analysis is done, one of the purposes of this study was to verify that their earlier 1930–65 results also hold for a more recent period (1950–70), and with improved data series.

I. The Labor Supply Equation

The basic labor supply equation to be used was put forward by Lucas and Rapping as part of a dynamic model of employment and unemployment. It was derived by assuming that households maximize utility by trading off present and future consumption and leisure. After aggregating over the entire economy and omitting the variables they found not to add significant explanatory power in the regressions, the following log-linear approximation resulted:

$$(1)\qquad N_t - M_t = b_0 + b_1 w_t - b_2 w_t^* + b_3(P_t - P_t^*)$$

Here, the b are positive constants, N represents the total employment in man-hours, M the population adjusted for age-sex distribution, w the real wage rate and P the price level. As is true throughout this paper, the variables are logarithms of the quantities represented.

The starred variables are actually intended to represent estimates of all future labor and consumption possibilities considered by the household. However, for computational convenience, and because no good model is at hand for making long-term predictions, in practice one may use a one-period planning horizon, giving

$$(2)\qquad w_t^* = E(w_{t+1}\mid t)$$

and a similar relation for P. The right-hand side of this equation is supposed to represent the expectation of w_{t+1}, given the values of the variables up to time t. This interpretation of the starred variables appears to match the intention of Lucas and Rapping's derivation. An alternative is available, however:

$$(3)\qquad w_t^* = E(w_t\mid t-1)$$

This interpretation is more consistent with the "natural rate hypothesis," and is also mentioned by Lucas and Rapping. Note that there is considerable conceptual difference between (2) and (3). Since b_1 and b_2 turn out to be nearly equal, using equation (2) would imply that employment is determined by $w_t - E(w_{t+1}\mid t)$, the negative of the expected increase in w between t and t+1. On the other hand, equation (3) would give $w_t - E(w_t\mid t-1)$, the degree to which the pres-

* Carnegie-Mellon University. I would like to acknowledge the helpful comments of Robert Lucas, Edward Prescott, and Leonard Rapping, all of Carnegie-Mellon University, and referees for this journal, on earlier drafts of this paper. Particular thanks are due to Prescott for the use of his adaptive regression program. I was supported during this research by a National Science Foundation Graduate Fellowship.

ent period differs from expectation ("surprise").[1] Although the regressions done by Lucas and Rapping could not distinguish these two interpretations, it will be seen later that it is possible to distinguish them. All that remains before an equation may be written which is sufficiently explicit for empirical test is to specify a model for expectations formation. The model used by Lucas and Rapping is adaptive expectations,[2]

$$(4)\quad E(w_t \mid t-1) = \lambda w_{t-1} + (1-\lambda)E(w_{t-1} \mid t-2) + \lambda'$$

and similarly for P. This is intended primarily as a psychological model, the expectation being read as actual subjective expectations, not any objective statistical estimator.[3] In the context of the natural rate

[1] Of course Lucas and Rapping's derivation of equation (1) no longer applies with this second interpretation. As will become clear later, the crucial difference between $E(w_t|t-1)$ and $E(w_{t+1}|t)$ is not the period predicted, but the period on which the prediction is based. Thus one might consider using $E(w_{t+1}|t-1)$. Because it is based on information from $t-1$ it will have the properties of the second interpretation and be empirically indistinguishable from it. But since it predicts w_{t+1}, it can be used with the original derivation. Another possibility for motivating equation (1) under the second interpretation is to begin directly with the assumption that there is a natural rate of unemployment. (See Donald Gordon and Allan Hynes for arguments relating to this.) When real wages or prices rise unexpectedly, workers will be deceived about what acceptance wage rate will maintain their optimum period of unemployment and will accept jobs more quickly than normal, hence raising employment. This is similar to the sort of job search model used, for example, by Dale Mortensen. However, Gordon and Hynes' arguments do not seem to be based on job search per se. Their view would allow some period of unemployment to be an optimal strategy even with perfect information if job offers at different wages become available randomly.

[2] Note that with this model, since w_t is not known at $t-1$,

$$E(w_{t+1} \mid t-1) = \lambda w_{t-1} + (1-\lambda)E(w_{t-1} \mid t-2) + 2\lambda'$$

Since this differs from $E(w_t|t-1)$ only by a constant it will be indistinguishable from it in the regressions. This justifies the comment made in fn. 1 about the equivalence of $E(w_{t+1}|t-1)$ and $E(w_t|t-1)$.

[3] John Muth showed that equation (4) is in fact the statistically optimal way to estimate w_t in the case that a natural rate mechanism is really applicable. This case may be expressed by

[3] Continued:

$$w_t = x_t + \lambda' + u_t$$
$$x_t = x_{t-1} + v_t$$

where x_t is the natural rate, and u_t and v_t are each a series of identically distributed serially independent random variables with mean zero. Although u_t and u_{t-1} (and also v_t and v_{t-1}) must be independent, u_t and v_t may be correlated to any degree, even perfectly. As is stated above, it is not necessary that these equations actually hold, since equation (4) is intended only as a model of subjective expectations. However, it seemed of some interest to know how well equation (4) would predict the actual wages and prices. Thus a non-linear regression was done on (4) in the form

$$\text{(a)}\quad w_t = \lambda w_{t-1} + (1-\lambda)w^*_{t-1} + \lambda' + u_t$$
$$\text{(b)}\quad w^*_t = \lambda w_{t-1} + (1-\lambda)w^*_{t-1} + \lambda'$$

λ and λ' were adjusted until the square error in (a) was minimized, (b) being used to define w^*_t. Several years before the beginning of the sample w^*_t was set equal to the actual value of w_t and equation (b) was iterated until the first value of w^*_t needed was found. The results of this non-linear regression show λ (the speed of adjustment) to be .60 for wages and 1.78 for prices. The trend terms, λ', are .031 and .026, respectively. This was based on the data referred to elsewhere in this report as *BLS* (see the Appendix for details). Satisfyingly large r-squares (.996 and .989) and small errors (.17 and .05 for λ, .002 and .005 for λ') were obtained, and the results appear insensitive to the initial approximation. But trials over subperiods of the 1950–70 range show that the uncertainties are considerably larger than the standard error estimates. For example using 1952–70 gives a λ_w of .92, and 1951–70 gives a λ_P of 2.20. Both of these are far outside the error limits of the 1950–70 results. The fact that λ_P is greater than 1.00 suggests that no natural rate mechanism is at work there. Rather than a tendency for prices to return to normal, apparently the reverse tendency exists! It is interesting in this context to note the results of the following three-equation macro-economic model:

$$\text{(a}'\text{)}\quad y_t = a(P_t - E(P_t \mid t-1))$$
$$\text{(b}'\text{)}\quad y_t + P_t = x_t$$
$$\text{(c}'\text{)}\quad x_t = x_{t-1} + u_t$$

where y_t is real national output, x_t is demand for nominal national output, and u_t is a series of identically distributed serially independent random variables with mean zero. Equation (a′) is just equation (1) ignoring the real wage term; (b′) asserts equality of supply and demand for national output; and (c′) represents demand for output as being a random walk, trends having been suppressed. The solution to these three equations can be expressed recursively as

$$E(P_t \mid t-1) = (1+a)P_{t-1} - aE(P_{t-1} \mid t-2)$$

Note that this has the form of adaptive expectations, but λ is greater than 1.00. (See Lucas for a full development of a similar model.)

hypothesis the expectation is to be seen as a slowly changing natural rate. λ represents the degree to which the predictions weight the actual past performance rather than the previous prediction (or natural rate).

II. Testing the Adaptive Expectations Model

The equation for adaptive expectations, (4), can be combined with (1) by a Koyck transformation to give a single equation suitable for estimation. The type of transformation used assumes that λ has the same value for w and P. Using the interpretation of w_t^* as $E(w_{t+1}|\,t)$, and the equivalent for P, gives

$$(5)\quad \begin{aligned} N_t - M_t = {} & (b_0\lambda - b_2\lambda' - b_3\lambda'') \\ & + (b_1 - \lambda b_2)w_t \\ & - (1-\lambda)b_1 w_{t-1} \\ & + (1-\lambda)b_3(P_t - P_{t-1} \\ & + (1-\lambda)(N_{t-1} - M_{t-1}) \end{aligned}$$

Using $E(w_t|\,t-1)$ gives

$$(6)\quad \begin{aligned} N_t - M_t = {} & (b_0\lambda - b_2\lambda' - b_3\lambda'') + b_1 w_t \\ & - (b_2\lambda + b_1(1-\lambda))w_{t-1} \\ & + b_3(P_t - P_{t-1})) \\ & + (1-\lambda)(N_{t-1} - M_{t-1}) \end{aligned}$$

Note that if all one has is regression results on these equations, there will be no way to tell equations (5) and (6) apart. The decision between the two interpretations of expectation will have to be based on other evidence.

Table 1 presents results of regressions based on these two equations, for three different sets of data. The first is Lucas and Rapping's original 1930–65 data, the results being taken directly from their paper. The second is their data extended by the author to cover the 1950–70 period. The third set of data covers the same 1950–70 period, but is based on data from the Bureau of Labor Statistics (*BLS*) not available for earlier periods. (See the Appendix for more details on the data.)[4] Knowledge of the way the data was derived, as well as the results in Table 1, suggest that the *BLS* data is more accurate, or at least more sensitive to short-term variations. This would explain the larger values of the three coefficients, the smaller values of the coefficient of the lagged dependent variable (which may have more weight thrown on it than that due to $(1-\lambda)$ when the model is bad), and the higher r-square in the estimation using the *BLS*

[4] Here, as in all other regression results, asymptotic estimates of the standard errors are given underneath each coefficient in parentheses. Also the r-square and Durbin-Watson statistics are given. In fact it is not certain just what the standard errors mean in simultaneous equation models with such a small sample size. However, I will follow the usual practice of ignoring this problem and treat the standard errors as real estimates of the standard errors of presumed normal distributions of the coefficients. Since there is little alternative, other than giving up any attempt to determine whether coefficients of two different regressions differ significantly, one may only hope that this interpretation is not misleading. Note that the usefulness of the estimates is even more dubious for the non-linear results described in fn. 3 and below.

[a] Standard errors are shown in parentheses.

data. For this reason the *BLS* data is used elsewhere in the paper. Lucas and Rapping's data was extended to 1970 to allow comparison between the two periods using the same data sources. It can be seen that the coefficients of wages, prices and expectations are nearly the same for the two periods, but that of the lagged dependent variable is not.

Table 1 shows two-stage least square regressions. The corresponding ordinary least square results are given in Table 2 for comparison, along with the reduced-form wage equation used for the wage term in the two-stage process. Since both wages and employment are determined in the labor market, there is undoubtably correlation between the wage and error terms in the ordinary least squares. The extent of this effect may be seen by comparing the two-stage results in Table 1 with the ordinary results in Table 2. It can be seen that the coefficients are larger (and more significant) and the r-square is larger for the two-stage.

It was suggested above that when the equation (5) or (6) does not fit the data very well, more weight is thrown on the coefficient of the lagged dependent variable than just $(1-\lambda)$. If so, it would be useful to have a way of testing equation (1) that did not introduce the lagged dependent variable. In fact such a way exists. The second line in Table 3 gives the results of a non-linear regression based on equation (1) directly, with w_t^* and P_t^* given by

$$(7)\quad E(w_t \mid t-1) = \lambda w_{t-1} + (1-\lambda)E(w_{t-1} \mid t-2)$$

and similarly for P.

The computer program used to produce those results searched for the values of λ_w and λ_P that minimize the squared error in equation (1) when equation (7) is used to define the expectations.[5] The agreement between these results and those based on equations (5) and (6) (repeated as the first line of Table 3) is encouraging. Note that the coefficient of the lagged dependent variable represents $(1-\lambda)$, hence λ is inferred to be .80, between the values of λ_w and λ_P coming from the non-linear regression.[6]

[5] Equation (7) differs from the equations (a), (b) in fn. 3 mainly in the lack of the trend term. This is incorporated in the intercept of the regression on equation (1), and is not separately identifiable. As in fn. 3, w_t^* is set to the actual value of w_t in some year before the start of the regression. Repeat runs using different years show that the results are not sensitive to what beginning period is chosen.

[6] These results have been given with the interpretation of P_t^* as $E(P_t \mid t-1)$, which is implicit in equation (7). The equivalent for $E(P_{t+1} \mid t)$ is

$$E(P_{t+1} \mid t) = P_t + (1-\lambda)E(P_t \mid t-1)$$

From this we see that $P_t - P_t^*$ would become

TABLE 3—TWO-STAGE REGRESSIONS ON VARIOUS VERSIONS OF LABOR SUPPLY EQUATIONS, *BLS* DATA[a]

	Regression Coefficient of N_t-M_t on:

[a] Standard errors are shown in parentheses.

There is a reservation about these results, however. Similar regressions were done for subperiods within the 1950–70 time span. They suggest that the error estimates for the λ may be understating the uncertainty. The values of λ from the linear regression are distributed between .70 and 1.33, and those of λ_w and λ_P in the non-linear regression between .69 and 1.00, and .75 and 1.36, respectively. The values greater than 1.00 all have rather large error estimates with them, and some of the regressions have as few as nine observations, so this large variation is not as bad as it looks. Nevertheless, it does cast some doubt upon the significance of the difference between the λ's and 1.00. Thus it seemed reasonable to test the hypothesis that λ is 1.00 for both w and P. This would mean the estimate is simply the previous period's value plus a trend term. The result of this is given as the third line of Table 3. The adjusted r-square and coefficient error estimates are not quite as good, and the Durbin-Watson statistic is noticeably worse. Nevertheless, the improvement does not seem to be enough to conclude that λ is really different from 1.00.[7] To give the reader a feeling for the degree of sensitivity to the exact period used, the next three lines of Table 3 repeat the first three, but with the period 1952–70.

Since we have concluded that the estimate of w or P is very nearly the last period's

$$P_t - E(P_{t+1} \mid t) = P_t - \lambda P_t + (1-\lambda)E(P_t \mid t-1) = (1-\lambda)[P_t - E(P_t \mid t-1)]$$

Clearly if we had used this interpretation, the coefficient of $P_t - P_t^*$, which is b_3, would have been larger by a factor of $1/(1-\lambda)$. On the other hand, the linear regression would have to be interpreted by equation (5) which has $(1-\lambda)b_3$ where equation (6) has b_3. Thus the predicted coefficient for the linear regressions would be the same. These results thus do not distinguish between equations (5) and (6) directly. Nevertheless, since $(1-\lambda)$ has different signs over different periods, the $E(P_{t+1}|t)$ interpretation would require b_3 to be changing signs the same way, clearly an unacceptable hypothesis. Thus we may regard the interpretation of P_t^* as $E(P_t|t-1)$ as being the correct one. A similar argument can be made for w_t^* if b_1 and b_2 are regarded as being equal. Certainly their ratio is small compared to $1/(1-\lambda)$, the critical ratio in the above argument.

[7] In any case, taking all of the regression results shown together it seems unlikely that λ is less than .7. Since the weight of each succeeding year in an adaptive model is decreased by a factor of $(1-\lambda)$, we may take $1/\lambda$ to be a time constant. A λ between .7 and 1.0 implies a time constant between 1.0 and 1.4 year. Clearly annual data is not well suited to make discriminations within this range.

value with a trend, there is another place adaptive expectations could be tried: the trend term. It would be reasonable to expect that term to adjust slowly to match the experienced trend. This would show up in these regressions as a change in the intercept. A test was done using a program written by Edward Prescott and Thomas Cooley. This program allows the intercept to change adaptively. The best predictions are when λ is zero for the intercept adaptation. It is not possible to quote a meaningful standard error for that estimate, but the conclusion seems to be that the existence of that type of adaptation is not supported by this evidence.

III. Discussion

It would appear that the labor supply model proposed by Lucas and Rapping (equation (1)) fits the facts of the recent *U.S.* economy fairly well. However, it should be interpreted as comparing actual wages and prices with those expected to prevail at the present time based on past information. Thus employment will differ from normal only when people are surprised by the wage or price level. This interpretation will probably require a new motivation to be developed for the equation. With that qualification, the results are quite impressive. The coefficients evaluated over the period 1930–65 agreed well with those of 1950–70. For periods including such different economic events, this is rather remarkable.

There is some trouble trying to draw definite conclusions about the expectation model. Adaptive expectations worked quite well, but λ (the weight put on the past period's actual value) had values which are nearly 1.00, and in fact probably cannot be distinguished from 1.00. No evidence was found that the expected trend moves adaptively, either, although better statistics might reverse that conclusion. The conclusion seems to be that any departures of expectations from last period's value plus a constant trend is due to long-term learning, and even then its effect has not clearly shown up here. This suggests that the Phillips curve tradeoff between inflation and unemployment may be real—if not permanent, at least over a period of years.

Before these conclusions are accepted, however, some limitations of this study should be considered. First, it uses annual data over a 21-year period. This makes the sample size too small to give strong statistical results. The consequences of using annual data for dynamic models are not clear yet, but may well be significant. Second, the 1950–70 period was rather placid economically. In trying to choose between expectations models it may well be necessary to use periods where there are fairly major events to adapt to. Somewhat related to this point is the possibility of a threshold of error in the learning of expectations: if the difference between people's expectations and reality is below this threshold, it might be assumed that no change will occur in the expectation scheme. Only when it exceeds this threshold will learning occur. If there is such a phenomenon, it will be particularly crucial to use a period with a great prevalence of surprising events. Otherwise no evidence at all may be found of learning or adaptation.

Appendix

Data Sources

All variables in the text represent logarithms of the raw data. The actual data are available from the author on request.

Lucas-Rapping Data, Extended to 1970 by Author

N = (number of persons engaged in production, Table 6.6, *Surv. Curr. Bus.*) $\times$(hours/yr by full-time employees, Denison, p. 37, normalized to 100 = 1929). The Denison series was extended beyond 1958 by regressing *BLS* weekly manufacturing hours on it (Table C-1, *Employment and Earnings*).

w = (compensation/full-time equivalent employee, Table 6.5, *Surv. Curr. Bus.*)/ (hours/year by full-time employees—as above)/P.

Q = index of effect of education on labor productivity, Dennison, p. 85. This series was extended beyond 1958 by linear extrapolation.

P = implicit price deflator on total GNP, 100 = 1958, see Table 8.1, *Surv. Curr. Bus.*

Classical Production Functions, Technical Optimality, and Scale Adjustments of the Firm

By DALE TRUETT AND BLAINE ROBERTS*

Recently, there has been renewed interest in relations among production functions, cost curves, and scale adjustments by firms in response to factor price changes. The current literature contains a number of efforts to clear up the connection between factor prices and output adjustments of the perfectly competitive firm.[1] In particular, Charles Ferguson and Thomas Saving have related adjustments in the size of the purely competitive firm in equilibrium to the expenditure elasticity of factors, and one of the present writers has demonstrated that expenditure elasticity can be determined from factor intensity elasticity or from the slope of the expansion path in a two-factor case. A similar proof has been provided independently by Lowell Basset and Thomas Borcherding.

In part, the general lack of understanding of the precise relations between production functions, cost curves, and scale adjustments stems from neoclassical theory's divergent paths, which led to both the intuitive appeal of U-shaped cost curves and the indeterminacy of the firm in the general equilibrium model formulated by Walras and popularized by Cassel. The confusion is exacerbated by the unfamiliarity of many American economists with the excellent technical treatise of Ragnar Frisch (first published in English in 1965) and by the scant opportunities for empirical evidence of U-shaped cost curves. Alan Walters, in his well-known survey of production function and cost function literature, notes " . . . there is no large body of data which contradicts the hypothesis of a U-shaped cost curve and the fruitful results which depend upon it" (p. 52). However, empirical methods have resulted in production functions of a very restrictive nature, for example, the familiar Cobb-Douglas. In an attempt to reconcile these empirical functions with classical functions producing U-shaped cost structures, various generalizations have been made; for example, *CES*, *VES*, and recently, homothetic production functions have been estimated.

This article has several purposes. First, we develop the concept of constant homogeneity contours in the isoquant map and present a classification of nonhomogeneous production functions which clarifies the relation between production and cost curves. Second, we relate constant homogeneity contours to expenditure elasticity of factors and demonstrate that the latter is a local phenomenon and subject, in general, to reversal. Factor expenditure elasticity thus proves to have limited usefulness for determining scale adjustments when factor prices change. Finally, in the appendixes to the paper, examples of various classical production functions are presented.

I. Constant Homogeneity Contours

For simplicity, and without loss of generality, assume the production function is of the following form:

$$x = f(a, b) \tag{1}$$

where x = output, a and b are factors of production, and the function is twice differentiable in the domain of a and b. In the

Saving, Hajime Hori, and anonymous referees for helpful suggestions on earlier drafts.

[1] Recent work pertaining to this issue includes not only analyses of scale adjustments per se but also examinations of the determinants of input demand. Contributions include those of Lowell Bassett and Thomas E. Borcherding, D. V. T. Bear, C. E. Ferguson and T. R. Saving, Paul Mayer (1968), and Trout Rader.

relevant region, the marginal products, f_a and f_b, are positive and isoquants are smoothly convex to the origin. Furthermore, for the region relevant to our discussion, the sufficient conditions for a profit maximum are assumed:

$$f_{aa} < 0, f_{bb} < 0, \text{ and } f_{aa}f_{bb} > f_{ab}^2$$

A constant homogeneity contour (*CHC*) is the locus of all points where the production function possesses the property of homogeneity of degree k, that is,[2] where[3]

$$kx = f_b b + f_a a \tag{2}$$

The slope of a *CHC*, which is in implicit functional form in (2), can be found by differentiating (2) and holding k constant, providing such a contour exists. Thus:

$$\begin{aligned} k(f_b db + f_a da) &= f_{bb}bdb + f_{ba}bda + f_b db + f_{aa}ada \\ &\quad + f_{ab}adb + f_a da, \end{aligned} \tag{3}$$

or solving for $\left.\frac{db}{da}\right|_k$, we have:

$$\left.\frac{db}{da}\right|_k = -\frac{f_{ba}b + f_{aa}a + (1-k)f_a}{f_{bb}b + f_{ab}a + (1-k)f_b} \tag{4}$$

If the function $x=f(a, b)$ is homogeneous at every point in the isoquant map, the derivative in (4) will be undefined (i.e., $db/da=0/0$). If, however, the function produces a U-shaped long-run average cost curve, (4) will be uniquely defined for every value of a and b in the relevant region. Furthermore, as one moves along any monotonically increasing path from the origin and as successive *CHC*s are intersected, k must be first greater than one, then equal to one, and finally less than one, corresponding to falling average cost, average cost equal to marginal cost, and increasing average cost. This class of functions will be termed "classical" functions.[4]

For classical functions, (2) will be a contour. Furthermore, when $k=1$, the contour will be the locus of points that are technically optimal, in the sense that they are the points at which average returns will be maximized or average cost (for any relative factor prices) minimized. This *CHC* will be termed the *technically optimal contour* (*TOC*), and its slope is:

$$\left.\frac{db}{da}\right|_{k=1} = -\frac{f_{ba}b + f_{aa}a}{f_{bb}b + f_{ab}a} \tag{5}$$

In general, *CHC*s may have any shape, and their slope could be either positive or negative without violating the above assumptions or the sufficient conditions for a profit maximum.[5] However, there are sufficient conditions for the *CHC* to be downward sloping and to either be coincident with isoquants or to cut isoquants from above or below. For example, if $f_{ab} \leq 0$ and $k \geq 1$, then the constant homogeneity contour will be downward sloping. Following Frisch, p. 123, since the homogeneity of the function at a point corresponds to the scale elasticity at that point, the region where $k>1$ will be designated the technically preoptimal region and where $k<1$, the technically postoptimal region. In the technically preoptimal region, long-run average cost will be falling, while in the technically postoptimal region long-run average cost will be increasing.

II. Relation of the Technically Optimal Contour to Isoquants

The technically optimal contour *TOC* determines the size of the purely competitive firm in equilibrium since it traces the locus of points where average returns are equal to

[2] k is mathematically equivalent to the scale elasticity (E_s) at a particular point in the isoquant map. That is:

$$dx = f_a da + f_b db$$
$$\frac{dx}{x}x = f_a a\frac{da}{a} + f_b b\frac{db}{b}$$

if $da/a=db/b=dk/k$ and since $E_s=(dx/dk)(k/x)$ then $E_s(x)=f_a a+f_b b$ or $E_s=k$.

[3] For the n-factor case, $x=f(a_1, \ldots, a_n)$, *CHC*s are the implicit functions $kf(a_1, \ldots, a_n)=\sum_{i=1} f_i c_i$.

[4] Frisch, p. 120, describes such a function as following the *regular ultra passum* law.

[5] That is, $f_{aa}f_{bb}>f_{ab}^2$ is neither necessary nor sufficient for $db/da|_k$ to be greater than, equal to, or less than zero. Levenson and Solon, p. 107, present what is equivalent to a *TOC* in their text, *Essential Price Theory*.

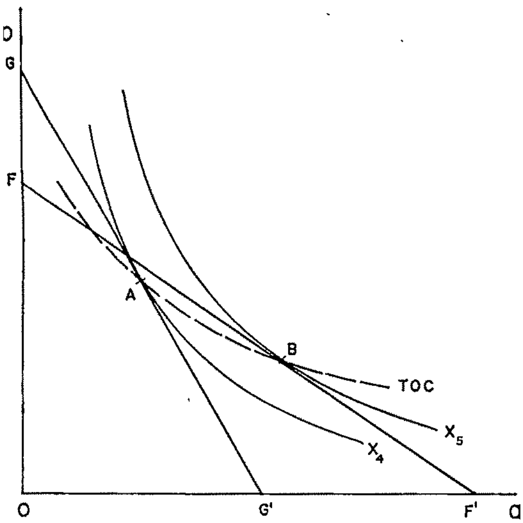

FIGURE 1. *VOS* PRODUCTION FUNCTION WHERE OPTIMAL SCALE INCREASES AS p_a/p_b FALLS

marginal returns. That is, the *TOC* traces out all points where the production function possesses the property of linear homogeneity. Thus, whether the *TOC* is coincident with or intersects isoquants from above or below will determine the change in size of the competitive firm in response to a change in factor price ratios.

It is useful to subdivide classical production functions into those with *variable optimal scale* (*VOS*) and those with *constant optimal scale* (*COS*). For *VOS* functions, the *TOC* will intersect isoquants, and in general, more than once. Figure 1 is an illustration of a variable optimal scale function where the *TOC* intersects isoquants only once. Points *A* and *B* represent the cost minimization points for factor price ratios given by the slopes of the budget lines *GG'* and *FF'*, respectively. Assuming that these are also points for which average total costs are a minimum (i.e., $k=1$), they will also lie on the *TOC*. Note that as p_a/p_b falls, optimal output increases.

It has been asserted in the literature that if a homothetic production function has an optimal scale under each price situation, then the optimal scale is the same for all price situations.[6] This is true, and in Appendix II, a proof is provided along with an example of a homothetic classical production function. Also, if *CHC*s are coincident with isoquants, then the expansion path (isocline) is a linear ray through the origin. More formally:

THEOREM 1: *If:*

$$\left.\frac{db}{da}\right|_k = \left.\frac{db}{da}\right|_{dx=0} \tag{6}$$

i.e., if

$$-\frac{f_{ab}b + f_{aa}a + (1-k)f_a}{f_{bb}b + f_{ab}a + (1-k)f_b} = -\frac{f_a}{f_b} \tag{7}$$

then

$$\sigma = \left.\frac{db}{da}\right|_{d(f_b/f_a)=0} = \frac{b}{a} \tag{8}$$

where σ is the slope of the expansion path.

PROOF:[7]

First note:

$$d\left(\frac{f_b}{f_a}\right) = \frac{f_{bb}db + f_{ab}da}{f_a} - \frac{f_b}{f_a^2}(f_{aa}da + f_{ab}db) \tag{9}$$

so that $d(f_b/f_a)=0$ implies

$$\sigma = \frac{f_b f_{aa} - f_a f_{ab}}{f_a f_{bb} - f_b f_{ab}} \tag{10}$$

[6] For example, see Meyer (1968, 1970). Meyer (1968) provides an example of a homothetic function, but it does not produce a U-shaped cost curve.

[7] This theorem can be proved for the n-factor case by beginning as follows. A point of tangency of the *TOC* and an isoquant is a solution to the system of homogeneous equations $\sum_i \sum_j f_{ij} a_j dx_i = 0$ and $\sum_i f_i dx_i = 0$. Thus if

$$\frac{\sum_j f_{ij}(\langle\bar{a}\rangle)a_j}{f_i(\langle\bar{a}\rangle)} = \frac{\sum_j f_{kj}(\langle\bar{a}\rangle)a_j}{f_k(\langle\bar{a}\rangle)} \quad \text{for all } i, k = 1, \ldots, n$$

holds for every vector of inputs $\langle\bar{a}\rangle$ such that $f(\langle\bar{a}\rangle) = \bar{y}$ (a constant), then the *TOC* is coincident with an isoquant.

From (7),

$$(11)\quad f_b f_{ab} b + f_b f_{aa} a + (1-k) f_b f_a = f_a f_{bb} b + f_a f_{ab} a + (1-k) f_b f_a$$

Thus,

$$(12)\quad \frac{f_b f_{aa} - f_a f_{ab}}{f_a f_{bb} - f_b f_{ab}} = \frac{b}{a}$$

It can easily be shown that the left-hand term of (12) is the slope of an isocline.[8] Also, any function with *CHC*s coincident with isoquants is homothetic. That is, if $x=f(a, b)$ and if the premises of Theorem 1 are true, then there exists some monotonic transformation, g, of a linearly homogeneous function $h(a, b)$ such that $x=g[h(a, b)]$. However, it does not necessarily follow that all *COS* functions are homothetic. That is, a production function may have its *TOC* coincident with an isoquant while other *CHC*s ($k \neq 1$) intersect isoquants.

III. The *VOS* Function and Factor Expenditure Elasticity Reversal

For a *VOS* production function, the *TOC* must intersect isoquants, and within the range of positive factor prices it *may* intersect some isoquants more than once. Figure 2 illustrates a case in which the *TOC* intersects an isoquant twice. If relative factor prices are given by the slope of GG', optimal long-run output will be x_3. Any fall in relative factor prices will result in an optimal output greater than x_3 as long as factor prices do not fall below the ratio given by FF'. If the factor price ratio does fall below OF/OF', optimal long-run output will be less than x_3. Thus from point C a fall in p_a, for example, could cause optimal output *either* to increase

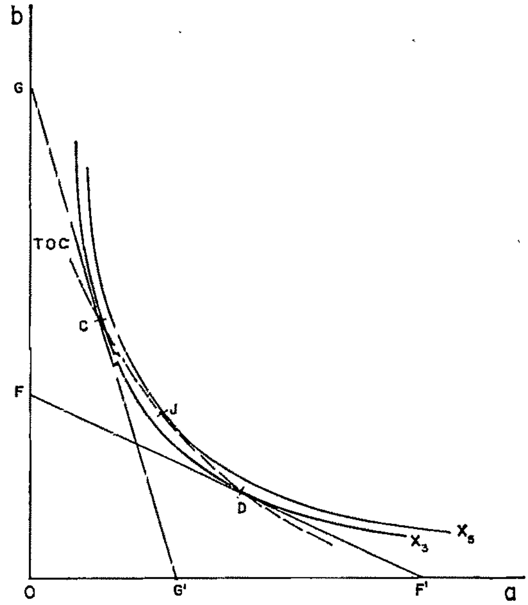

FIGURE 2. *VOS* PRODUCTION FUNCTION WITH A MAXIMUM OPTIMAL OUTPUT AND EXPENDITURE ELASTICITY REVERSAL

or to decrease depending upon the magnitude of the price change. Further, in Figure 2 at J there exists a factor price ratio which will yield the *maximum* optimal output in the long run. Thus, if a *VOS* function has a point such as J within the range of possible factor prices, the perfectly competitive firm will not produce a long-run output greater than the level consistent with that point. In Appendix I we provide an example of a *COS* production function with a maximum optimal scale.[9]

From the foregoing, it is evident that there is no general relation between a change in the price of a given factor and adjustment of optimal output for a *VOS* production function. Optimal output may either rise or fall when a factor price changes, depending upon the exact *form* of the production function and the *magnitude* of the change in price. Indeed, when a long-run equilibrium occurs at a point of tangency between the *TOC* and an

[8] For $x=f(a, b)$ and from the necessary conditions for minimum cost where $c=ap_a+bp_b$ is total cost, let

$$Z = \frac{f_a}{f_b} - \frac{p_a}{p_b} = 0, \quad \text{then}$$

$$\frac{dZ}{da} = \frac{f_{aa}}{f_b} + \frac{f_{ab}}{f_b}\frac{db}{da} - \frac{f_a f_{ab}}{f_b^2} - \frac{f_a f_{bb}}{f_b^2}\frac{db}{da} = 0$$

Solving for db/da, we obtain

$$\frac{db}{da} = f_b f_{aa} - f_a f_{ab} / f_a f_{bb} - f_b f_{ab}$$

[9] The reverse case of Figure 2 is also possible. The *TOC* may intersect isoquants twice and be tangent to one which is a *minimum* output for the perfectly competitive firm in long-run equilibrium.

isoquant such as J in Figure 2, *any* change in relative factor prices will reduce long-run optimal output.

In their article on scale adjustments, Ferguson and Saving conclude that when a single input price changes, adjustments in long-run optimum output depend upon the expenditure elasticity of the price-changing input. Let

$$S_a = \frac{c}{a}\,\frac{da}{dc} \tag{13}$$

be the expenditure elasticity of input a, where

$$c = ap_a + bp_b \tag{14}$$

is total cost. Assuming $S_a > 0$, factor a is normal, neutral, or superior as $S_a \lesseqgtr 1$. In the event that $S_a < 0$, factor a is inferior.

Ferguson and Saving state:

> [The] long-run equilibrium output of a perfectly competitive firm must always vary directly with the price of an inferior or normal input and must always vary inversely with the price of a superior input. [p. 777]

The above is correct, but it is necessary to indicate that the expenditure elasticity of a factor may *reverse* over the range of an observed price change, thereby rendering impossible the prediction of scale adjustment from expenditure elasticity and direction of factor price change.

For normal factors of production, we can, however, determine the relation of expenditure elasticity to isoquants and the technically optimal contour. Specifically, at any technically optimal point for a downward sloping TOC, if the slope of the TOC is greater than the slope of an intersecting isoquant, then the expenditure elasticity of factor a is greater than one. Recalling from (8) that σ denotes the slope of the expansion path, it can be shown that if:

$$\left.\frac{db}{da}\right|_{k=1} > -\frac{f_a}{f_b} \tag{15}$$

then[10]

$$\sigma < \frac{b}{a} \tag{16}$$

Let the factor intensity elasticity (elasticity of expansion) be

$$E_L = \frac{\sigma}{b/a} \tag{17}$$

as defined previously in a paper by Truett. From the foregoing, the numerator of (17) is the slope of the expansion path, while the denominator is the factor ratio. If $E_L < 1$, production becomes more a-intensive as the firm expands at given factor prices; the converse is true if $E_L > 1$. In the former case the proportion of total outlay spent for a increases, while that spent for b falls. Thus, $S_a > 1 > S_b$. This can be easily shown. Since:

$$S_a = \frac{c}{a}\,\frac{da}{dc} = \frac{p_a + p_b(b/a)}{p_a + p_b\sigma} \tag{18}$$

S_a must be greater than one if $E_L < 1$. Thus, at any point where a downsloping TOC cuts an isoquant from below, factor a is superior while factor b is normal. This is the case at points A and B in Figure 1 and at point C in Figure 2. However, by similar reasoning when the TOC cuts an isoquant from *above* (such as point D in Figure 2), $E_L > 1$ and

[10] Since $-\dfrac{f_{ab}b + f_{aa}a}{f_{bb}b + f_{ab}a} < 0$,

either: or:

I. $f_{bb}b + f_{ab}a < 0$, $f_{ab}b + f_{aa}a < 0$

II. $f_{ab}b + f_{aa}a > 0$, $f_{bb}b + f_{ab}a > 0$

II. implies $f_{aa}f_{bb} < f_{ab}^2$ and violates the sufficient conditions for a profit maximum. Therefore, using I. and if

$\left.\dfrac{db}{da}\right|_{k=1} > -\dfrac{f_a}{f_b}$, then $(f_{aa}f_b - f_{ab}f_a)a > b(f_af_{ab} - f_bf_{ab})$.

Since

$$\sigma = \frac{(f_bf_{aa} - f_af_{ab})}{(f_af_{bb} - f_bf_{ab})} > 0,$$

the numerator and denominator must be of the same sign. Therefore, both numerator and denominator must be negative for the sufficient conditions for a profit maximum to hold and, in particular, $f_af_{bb} - f_bf_{ab} < 0$. Consequently, it follows that $\sigma < b/a$.

$S_b > 1 > S_a$. In fact, it is evident that J in Figure 2 is a point of expenditure elasticity reversal, since a fall in p_a will cause optimal output to increase from higher points along the *TOC*, but will cause optimal output to fall below J. At this juncture, we can state:

THEOREM 2: *If:*

$$(19) \qquad \left.\frac{db}{da}\right|_{k=1} < 0; \qquad \sigma > 0; \quad and$$

$$\left.\frac{db}{da}\right|_{k=1} \gtrless -\frac{f_a}{f_b};$$

then:

$$(20) \quad E_L \lesseqgtr 1 \quad and \quad S_a \gtreqless 1 \quad while \quad S_b \lesseqgtr 1;$$

which is proved by the foregoing argument.[11]

Also, at points such as A and B in Figure 1 (C in Figure 2), the expansion path (not shown in figures) is less steep than a factor-ray through the origin, since $\sigma < b/a$. In other words, where the *TOC* intersects isoquants from *below*, the slope of isoclines will be less than the slope of a ray through the origin; the reverse will be true if the *TOC* intersects isoquants from *above* (at D in Figure 2, for example). Since ridge lines are isoclines, this suggests that the "textbook" nonhomogeneous function with inward-bending ridge lines (see James Henderson and Richard Quandt, p. 48, or Albert Levenson and Babette Solon, p. 107) is characterized by expenditure elasticity reversal of factors and isoquants which intersect the *TOC* more than once. Appendix I provides an example of such a function.

IV. Summary and Conclusions

Classical production functions are those which produce U-shaped long-run average cost curves. When such functions are examined in terms of contours for constant homogeneity, as output increases the degree of homogeneity, k, is initially greater than one but decreases and becomes less than one. Where $k=1$, marginal and average returns are equal, and points of technical optimality occur on the function. Regardless of factor prices, minimum long-run average cost will correspond to some factor combination on the locus of technically optimal points, the technically optimal contour. If the *TOC* is a single isoquant, the production function will have a constant optimal scale, and optimal output will be the same for all factor prices. On the other hand, when the *TOC intersects* isoquants, a change in relative factor prices will cause optimal output to increase or decrease. If the *TOC* cuts each isoquant only once, the change in optimal output following a factor price change will depend upon the direction of the price change and whether the *TOC* cuts isoquants from above or below. In this case, the direction of scale adjustment can be unambiguously predicted from the expenditure elasticity of the price-changing factor. In the event that the *TOC* intersects isoquants twice or more, *magnitude* as well as direction of factor price change is important to the outcome. This final case is characterized by expenditure elasticity reversal. Here, factor expenditure elasticities are meaningful only in a local context and provide no clue to the perfectly competitive firm's scale adjustment when a finite factor price change occurs.

APPENDIX

I. Nonhomothetic Classical *VOS* Function with Expenditure Elasticity Reversal

A variable optimal scale function similar to that of Figure 2 above can be specified by adding internal economies and diseconomies to a linearly homogeneous production function. The function introduced by Ryuzo Sato in a series of exchanges some years ago in this *Review*, provides a precise textbook example of the linearly homogeneous production function, since it produces a "Knightian" total product curve for the short-run variable factor. Although it is desirable heuristically that the classical *VOS* function have short-run properties similar to the Sato function, the *VOS* function, by definition, will be nonhomogeneous.

The following modified Sato function will fit the *VOS* function in Figure 3:

[11] This theorem also can be generalized to the n-factor case in a straightforward manner.

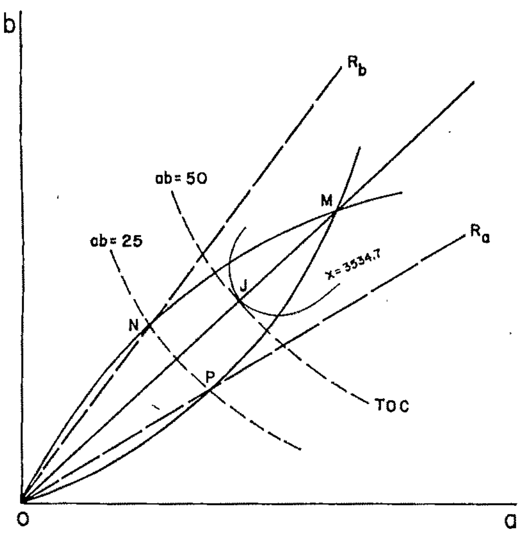

FIGURE 3. MODIFIED SATO FUNCTION WITH VARIABLE OPTIMAL SCALE AND EXPENDITURE ELASTICITY REVERSAL

$$\text{(I.1)} \qquad \frac{(ab)^2}{Da^3 + Eb^3} + (Fab - Ga^2b^2)$$

where $D=E=.001$, $F=.5$, and $G=.01$. The disturbance term $(Fab-Ga^2b^2)$ can be viewed as the combined effect of internal economies and diseconomies, an effect which will be positive at low values of ab but negative when ab is relatively large. The combined disturbances will equal zero when

$$\text{(I.2)} \qquad ab = F/G = 50$$

or along a rectangular hyperbola in the isoquant map. At any point on this contour (the TOC), the function will behave as the original Sato function. Further, when $F/2G = ab = 25$, there will be no disturbance to the Sato marginal products; thus the original Sato ridge lines (R_a and R_b) cross those for the modified function where the rectangular hyperbola $ab=25$ also intersects the latter.

At the point of maximum optimal scale, the absolute slope of an isoquant must equal that of a factor ray. For the parameters specified above, this occurs when:

$$\text{(I.3)} \qquad b/a = \sqrt[3]{D/E} = 1$$

However, for all values of $b/a=1$ between the origin and M, Theorem 1 holds. That is, if a CHC is tangent to an isoquant for the modified Sato function, then:

$$\text{(I.4)} \quad b/a = \sqrt[3]{D/E} = 1 \qquad \text{if } D = E$$

It follows that tangencies between CHCs and isoquants occur all along OM in Figure 3. In the relevant range above OM, all isoclines are shaped like ridge line ONM; thus $S_a > 1 > S_b$ and CHCs cut isoquants from below. Below OM, isoclines are shaped like ridge line OPM, and $S_b > 1 > S_a$ while CHCs cut isoquants from above. It is evident that all points of expenditure elasticity reversal occur along OM, and for the parameters specified above, maximum optimal scale occurs at J where $a=b=7.07$. and output is 3,534.7 units of x.

II. Homothetic Classical Production Functions

Intuitively, a homothetic classical production function must have constant optimal scale because the transformation f in $x=f[h(a, b)]$ where h is homogeneous only "relabels" isoquants but does not change their shape. In other words, if the transformation f creates technical optimality for $\bar{a}, \bar{b}$, then it must do so for all $h(a, b)=h(\bar{a}, \bar{b})$. A formal proof and example follow.

THEOREM 3: *A homothetic production function has constant optimal scale; that is, the technically optimal contour is coincident with an isoquant.*

PROOF:

By definition, x is homothetic if $x=f[h(a, b)]$ where $h(a, b)=ah_a+bh_b$. Therefore, the technically optimal contour is

$$\left.\frac{db}{da}\right|_{k=1} = -\frac{f'bh_{ba} + bh_bh_af'' + f'ah_{aa} + af''h_a^2}{f'bh_{bb} + bf''h_b^2 + f'ah_{ba} + ah_ah_bf''}$$

Since h is homogeneous,

$$ah_{aa} + bh_{ab} = bh_{bb} + ah_{ab} = 0$$

$$\left.\frac{db}{da}\right|_{k=1} = -\frac{h_b h_a b + h_a^2 a}{h_b^2 b + h_a h_b a} = -\frac{h_a}{h_b}$$

An example of a homothetic classical production function is

$$x = a^\alpha b^\beta - ca^{2\alpha} b^{2\beta}$$

where $\alpha > 0$, $\beta > 0$, $\alpha + \beta > 1$, $c > 0$, and the function is defined for the region where $a \geq 0$, $b \geq 0$, and $a^\alpha b^\beta \leq 1/c$. If we let $a^\alpha b^\beta = f$, then $x = f - cf^2$, and f is a Cobb-Douglas function with homogeneity of $\alpha + \beta$. Since

$$\frac{x_a}{x_b} = \frac{\alpha a^{\alpha-1} b^\beta - 2\alpha c a^{2\alpha-1} b^{2\beta}}{\beta a^\alpha b^{\beta-1} - 2\beta c a^{2\alpha} b^{2\beta-1}} = \frac{\alpha b}{\beta a}$$

the function is clearly homothetic. The slope of the *TOC* is:

$$\left.\frac{db}{da}\right|_{k=1}$$

$$= -\frac{\alpha b}{\beta a} \frac{[\alpha + \beta - 1 - 2ca^\alpha b^\beta (2\beta + 2\alpha - 1)]}{[\alpha + \beta - 1 - 2ca^\alpha b^\beta (2\alpha + 2\beta - 1)]}$$

$$= -\frac{\alpha b}{\beta a}$$

Thus, the *TOC* is indeed coincident with an isoquant.

Peasants, Procreation, and Pensions: Note

By Clive Southey*

In his recent article in this *Review*, Philip Neher attempts to demonstrate rigorously that there is substance to the allegation that underdeveloped nations frequently have unduly high birth rates in order to satisfy the "pension motive," that is to say, parents have children to guarantee that someone will provide for them in their old age.

Neher's analysis is fairly general but he feels that the case which "particularly merits attention" is that in which egoistic parents care only for their own utility, having little regard for the world subsequent to their own deaths. This case exemplifies " . . . the *fundamental market failure* which exists when the consequence of current decisions carry beyond the decision makers' planning horizon" (p. 386). At this point, Neher adds in a footnote: "Note that this occurs independent of 'like father like son' effects. This model takes the fertility of future generations as exogenous" (fn. 16, p. 386).

In this footnote Neher uncovers a basic deficiency of his model, for to suggest that the number of grandchildren I have will be independent of the number of children I produce, is too unrealistic and particularly so in an economy which achieves a steady state. To note as Neher does that "There seems no very good way to make future fertility endogenous . . . " (fn. 7, p. 382) is not sufficient justification for making these decisions exogenous. This paper demonstrates that if a steady state were to prevail, such that succeeding generations learn that a "like father like son" mentality was prevailing, *there might be no market failure precisely in the case of egoistic parents.*

To demonstrate this we follow Neher's model and notation closely and confine ourselves to the case where $U=U(C_1)+U(C_2)$, so that although equal weight is given to adulthood and grand-parenthood $(D=1)$ future generations and even the utility of one's children while alive matter not at all $(E=0)$. If parents believe that their children will make the same decisions as they do, a belief that is not necessarily true, then Neher's equation (2) remains unchanged as follows:

$$C_1 = \frac{\overline{X}}{P_1} = \frac{f(\overline{F}_1)}{S_1 + \overline{F}_1 + \overline{G}_1} \tag{2}$$

However, his equation (3) under his simplifying assumption of certainty of survival will now read:

$$C_2 = \frac{X_2}{P_2} = \frac{f(S_1)}{2S_1 + \overline{F}_1} \tag{3}$$

It follows that Neher's equations (5) and (6) will become:

$$\frac{dC_1}{dS_1} = -\frac{1}{P_1}C_1 = -\frac{1}{P_1}\cdot\frac{f(\overline{F}_1)}{P_1} \tag{5}$$

and

$$\frac{dC_2}{dS_1} = \frac{(2S_1 + \overline{F}_1)f'(S_1) - 2f(S_1)}{(2S_1 + \overline{F}_1)^2} \tag{6}$$

Now according to Neher, in an economy obeying the "Golden Rule of Fertility" so that the population enjoys maximum sustainable level of per capita income, the average product of labor $f(S_1)/S_1$ is equal to the wage rate which is also equal to the marginal product of labor: $w=f'(S)$. Furthermore with a steady-state population $G_1=F_1=S_1=S_2$.

Thus substituting in (5) and (6) we obtain

$$\begin{aligned}\frac{dC_2}{dC_1} &= \frac{-(3S_1)^2}{f(S_1)}\cdot\frac{3S_1\cdot w - 2f(S_1)}{(3S_1)^2} \\ &= \frac{-3f(S_1) + 2f(S_1)}{f(S_1)} \\ &= -1\end{aligned}$$

* Assistant professor, University of Guelph.

This, however, is precisely the condition cited by Neher for nonviolation of the Golden Rule (p. 385). Hence, we have proven that the pension motive is consistent with the Golden Rule in this instance.

The above analysis is simply a statement about the possible existence of an equilibrium at the Golden Rule. It remains to consider whether this equilibrium is stable. We do not present an exhaustive treatment of this difficult problem, but the following analysis suggests that if the system is disturbed by say an exogenous technical change, it will move towards the new Golden Rule population.

We continue to assume that parents believe their children will simply reproduce themselves. Although this belief will be clearly contradicted by experience during any adjustment process, it would still appear to be more plausible than Neher's assumption that the number of grandchildren is determined exogenously.

If the economy is initially in a steady state with certainty of survival then $\overline{F}_1=\overline{G}_1$ so that with egoistic parents, the first-order conditions for the optimum as in (5) and (6) above can be reduced to

$$(7) \quad \frac{f(\overline{F}_1)}{(S_1+2\overline{F}_1)}=\frac{(2S_1+\overline{F}_1)f'(S_1)-2f(S_1)}{(2S_1+\overline{F}_1)}$$

If $S_1 \gtreqless F_1$ then $(2S_1+\overline{F}_1) \gtreqless (S_1+2\overline{F}_1)$ and thus by examining the differences in magnitude of the two numerators in (7) we can ascertain whether changes in population are consistent with the stability hypothesis. If (7) is satisfied, it follows that for consistency,

$$(8) \qquad S_1 \gtreqless F_1$$

$$\text{if} \quad (2S_1+\overline{F}_1)f'(S_1)-2f(S_1)-f(\overline{F}_1) \gtreqless 0$$

Consider technical changes such that the new Golden Rule population exceeds that prevailing at present. It follows that the average productivity of labor at existing population levels and for small increments therein, is less than the marginal product $f(S_1)/S_1<f'(S_1)$.

Rearranging terms in (8) and dividing through by S_1 we get

$$(9) \qquad S_1 \gtreqless F_1 \qquad \text{if} \left\{2f'(S_1)-\frac{2f(S_1)}{S_1}\right\} + \left\{\frac{\overline{F}_1}{S_1}f'(S_1)-\frac{f(\overline{F}_1)}{S_1}\right\} \gtreqless 0$$

The proof that in fact population will expand follows by contradiction. Suppose that decisions are made such that $S_1<F_1$; the first term of (9) is always positive. The sign of the second term is invariant when multiplied by $S_1/\overline{F}_1$ which yields

$$f'(S_1)-\frac{f(F_1)}{F_1}$$

and a sufficient (but not necessary) condition for this to be positive is that $f''(S_1)$ is negative. Since this is certainly true for small deviations from the Golden Rule population, it follows that the entire expression in (9) is positive; this however, contradicts the first-order conditions for population constancy or decrease and thus we must conclude that in fact population will expand. A similar argument follows for the case when the technical change calls for a decrease in Golden Rule population, and thus stability follows: not only is a share-alike system with egoistic parents consistent with the Golden Rule but it will also achieve that rule as long as parents subscribe to the belief that their children will behave in a "like father like son" manner.

By making future populations independent of the number of children born, Neher has only allowed for a "one-way" externality. What he therefore fails to incorporate is the fact that without malice, the children of peasants will in turn impose an externality on their parents by also having children and so reducing the grandparents' share; the absence of private pension schemes and the share-alike mentality is a double-edged sword that cuts both ways. It is of particular interest that in this one instance of egoistic parents, the result is compatible with the so-called Golden Rule of Fertility. Clearly this result is dependent on the specific assumptions made ($p=g=D=1$, and $E=0$ in Neher's model) as well as the as-

sumption that grandchildren claim as much of the output as do grandparents. That these *ad hoc* assumptions happen to be compatible with the Golden Rule should not detract from the potential that Neher's model has for further investigation of the role of institutions on fertility decisions. Nevertheless, at this juncture there is no a priori theoretical justification of the pension motive being a cause of "over population."

Stochastic Dominance, Efficiency Criteria, and Efficient Portfolios: The Multi-Period Case

By HAIM LEVY*

The theoretical and the empirical work in the theory of investment decision making under conditions of uncertainty (particularly in portfolio-selection theory) has been done so far under the very restricting assumption that all investors have a single target date for wealth accumulation, or investment horizon. They buy their portfolios on the same date with the object of maximizing their expected utility from terminal wealth.[1] The papers of James Tobin and Jan Mossin who deal with the multi-period mean-variance criterion are the exception.

The assumption of a single target date for wealth accumulation is unrealistic since investors usually have different planning horizons. Some tend to favor short-term investments, while others (particularly institutional investors) tend to invest in long range ventures.[2]

The purpose of this paper is to analyze the relationship between the efficient set of portfolios constructed for different investment horizons. More specifically, we assume that all investors of a given class (for example, risk averters) can choose between only two portfolios with well-defined distributions F_1 and G_1, whose one-period return is given by the random variables X_1^F and X_1^G, respectively. Now, if all investors have the same investment horizon, for example, one year, then they are confronted with the same set of distributions, and hence they will all choose the same efficient set. However, if the investment horizon of some investors is, say, two years, these investors are confronted with distributions $F \equiv F_1F_2$ and $G \equiv G_1G_2$, derived from the one-period distributions.[3] The return on the two-year portfolios are given by $X_1^FX_2^F$ and $X_1^GX_2^G$, respectively, and obviously, the distribution of X_1^F (or X_2^F) is not identical to the distribution of $X_1^FX_2^F$.[4] Consequently, although all investors are confronted with the same set of one-period available portfolios, this set is completely different from the available set of portfolios of the multi-period investors. Since the efficient set of portfolios is a subset of all available portfolios, one would expect the efficient set to be a function of the investment horizon—i.e., investors for one year might decide that portfolio F_1 is included in the efficient set and G_1 is not, while two-period (or multi-period) investors might reach the opposite decision.

In this article we analyze the role of the investment horizon in determining the efficient set. Apart from the obvious theoretical importance of the above analysis, it may also have some practical merit: suppose that

[2] In the conventional model of the theory of investment there is no constraint on the length of the period.

[3] We assume that the returns in period 1 and in period 2 are independent. Notice, also, that we assume that the investor chooses the same investment for the whole period; hence, in this model, portfolios F_1G_2, G_1F_2 are not permissible. This means that at the time that the decision is made, the investor does not intend to switch portfolios. Of course, after the first period is over the investor realizes the first-period return and he may change his estimates as well as his portfolio. In this case, the whole process of finding the efficient set starts again at the beginning of the second period.

[4] Moreover, in the general case, the distribution of X_1^F and the distribution of $X_1^FX_2^F$ do not even belong to the same statistical family. For example, if X_1^F and X_2^F have identical normal distributions, the random variable $X_1^FX_2^F$ is not distributed according to the Normal Law.

an investment consultant tries to screen all available portfolios—i.e., to build the efficient portfolio set for his customers. What will be the impact of various investment horizons on his final advice? Should he construct the same efficient set for all his customers, or should he build different efficient sets for investors with different investment horizons?[5]

Section I of this study gives a short review of two efficiency criteria that have been developed for the one-period case. In Sections II and III we analyze the two multiperiod efficiency criteria. Concluding remarks are given in Section IV.

I. Efficiency Criteria—The One-Period Case

An efficiency criterion is a rule with which we divide all the available portfolios into two groups—the efficient set and the inefficient set; for every portfolio included in the inefficient set, there is at least one preferable portfolio in the efficient set. Obviously, we have more than one criterion, and by changing the assumptions concerning the investors' preferences, one might get several efficiency rules (and, hence, several efficiency sets). However, given a set of assumptions on the investors' utility function, the criterion that minimizes the size of the efficient set is the *optimal* efficiency criterion.

A. *General Efficiency Criterion*

In the most general case, where investors are assumed to have no systematic preferences with respect to risk (i.e., no restrictions are placed on investors' utility function beyond the assumption that their first derivatives be nonnegative), it has been proved (see articles by James Quirk and Rubin Saposnik, Joseph Hadar and William Russell, and Giora Hanoch and Levy) that option F eliminates option G from the efficient set (i.e., F dominates G, or FDG) for all (utility) functions $\phi(x)$ (where $\phi'(x)$ is positive and continuous throughout the domain of x) if, and only if, $F(x) \leq G(x)$ for all values of x, and $F(x_0) < G(x_0)$ for some value x_0, where F and G denote the cumulative distributions of the two options under consideration. That is to say,

(1) $F(x) \leq G(x)$ for all values of x

and $F(x_0) < G(x_0) \Leftrightarrow$

$\Delta E\phi \equiv E_F\phi(x) - E_G\phi(x) \geq 0$, for all $\phi(x)$ and for some nondecreasing utility function $\Delta E\phi > 0$.

B. *Efficiency Criterion in the Case of Risk Aversion*

Under conditions of risk aversion—i.e., when one assumes a nondecreasing concave utility function ($\phi'(x) > 0$, $\phi''(x) < 0$ and $\phi'(x)$ and $\phi''(x)$ are continuous throughout), it has been proved that option F dominates option G (i.e., F eliminates G from the risk averters efficient set) if, and only if, $\int_{-\infty}^{x} [G(t) - F(t)]dt \geq 0$ for all values of x (and $G \neq F$ for some value x_0). This rule can be written as:

(2) $$\int_{-\infty}^{x} [G(t) - F(t)]dt \geq 0 \text{ for every } x$$

with a strong inequality for some $x_0 \Leftrightarrow$

$\Delta E\phi \equiv E_F\phi(x) - E_G\phi(x) \geq 0$, for every $\phi(x)$, with $\phi'(x) > 0$, $\phi''(x) < 0$, and for some nondecreasing concave utility function $\Delta E\phi > 0$.

For the purpose of this paper, another version of (2) should be developed. The right side of (2) is, by definition,

$$\Delta E\phi \equiv E_F\phi(x) - E_G\phi(x) = \int_{-\infty}^{\infty} [f(t) - g(t)]\phi(t)dt$$

where f and g stand for the density functions of the two options, respectively. Integrating by parts yields,

$$\Delta E\phi \equiv \int_{-\infty}^{\infty} [f(t) - g(t)]\phi(t)dt = \{[F(x) - G(x)]\phi(x)\}_{-\infty}^{+\infty} + \int_{-\infty}^{\infty} [G(t) - F(t)]\phi'(t)dt$$

[5] We shall assume, as in the one-period case, that the investor does have a certain future point of time in which he is willing to maximize the utility of his wealth. But unlike the one-period case, the horizons should not be identical for all investors.

Since the first term on the right side vanishes[6] we can replace (2) by (2′)

$$\int_{-\infty}^{x}[G(t) - F(t)]dt \geq 0 \tag{2′}$$

for every x (with strong inequality for some x)$\Leftrightarrow$

$$\int_{-\infty}^{\infty}[G(t) - F(t)]\phi'(t)dt \geq 0$$

for every nondecreasing concave $\phi(x)$.

We shall use these results in the following sections.

II. Multi-Period Dominance in the Case of an Unrestricted Utility Function

In the rest of the paper we shall prove several theorems, first for the two-period horizon, and then the results will be generalized for an n-period horizon. Like Tobin, we assume independence over time. More precisely, we accept the Random Walk Theory (see, for example, Paul Cootner).

Let R_i denote the return on one dollar invested in period i. The final wealth for an n-period horizon is therefore given by $1+R=\prod_{i=1}^{n}(1+R_i)$. Denoting[7] $1+R_i\equiv x_i$, the joint density function of $\prod_{i=1}^{n}x_i$ is $f(x_1, \ldots, x_n)$. Accepting the Random Walk hypothesis, the joint density function can be written as $f(x_1, \ldots, x_{n-1})f(x_n)$, since $f(x_n)$ is independent of $f(x_1, \ldots, x_{n-1})$. For the two-period case, independence implies $f(x_1, x_2)=f(x_1)f(x_2)$.

THEOREM 1: *A sufficient condition for a two-period risk $F(x)$ to dominate another two-period risk $G(x)$, for all nondecreasing utility functions, is:*[8] *F_iDG_i $(i=1, 2)$, where F_i and G_i denote the single period distributions.*

PROOF:

Let x_1 and x_2 be two continuous random variables for periods 1 and 2, respectively, and $x=x_1x_2$ is the random variable (return) for the two periods. Since F_iDG_i $(i=1, 2)$, it is given that:

$$F_1(x_1) \leq G_1(x_1) \quad \text{for every } x_1 \tag{3}$$
$$\text{and } F_1(x_{1_0})<G_1(x_{1_0}) \quad \text{for some } x_{1_0}$$

$$F_2(x_2) \leq G_2(x_2) \quad \text{for every } x_2 \tag{4}$$
$$\text{and } F_2(x_{2_0})<G_2(x_{2_0}) \quad \text{for some value } x_{2_0}$$

Assuming independence over time, the distribution function of the *two-period* return is given by:

$$\begin{aligned} F(x) &= P_r(x \leq x) \\ &= \int_0^{\infty}\int_0^{x/x_1} f_1(t_1)f_2(t_2)dt_2dt_1 \\ &= \int_0^{\infty} F_2(x/t_1)f_1(t_1)dt_1 \end{aligned} \tag{5}$$

Similarly, the distribution function of option G is given by:

$$G(x) = \int_0^{\infty} G_2(x/t_1)g_1(t_1)dt_1, \tag{6}$$

where f_i, g_i stand for the density functions of the two risks in period i.

We must prove that the two-period distribution F, dominates the two-period distribution G, i.e., $F(x)\leq G(x)$ for every x, and $F(x_0)<G(x_0)$ for some value x_0. Using (5) and (6) one has to prove that (7) holds,

$$\int_0^{\infty} F_2(x/t_1)f_1(t_1)dt_1 \leq \int_0^{\infty} G_2(x/t_1)g_1(t_1)dt_1 \tag{7}$$

[6] If $F(x)$ and $G(x)$ are finite, this term obviously equals zero. If $F(x)$ and $G(x)$ are infinite (for example, have normal distributions), the proof that this term equals zero is a bit more complicated.

[7] It is clear from the above definition that $0\leq x<\infty$, the lowest possible return in each period is $R_i=-1$, i.e., the stock price drops to zero. Obviously, if we have a distribution with $P_r(x_i=0)=1$, this portfolio is excluded from the efficient set and we shall not deal below with such degenerate distributions. By the same argument, we can assume that $P_r(x\geq M)=0$, where M is a large number.

[8] F dominates G (or FDG) means that every investor in a given class (e.g., all nondecreased utility functions) prefers option F over option G, and hence G can be eliminated from the efficient set. In other words FDG implies that $E_F\phi(x)\geq E_G\phi(x)$ for all $\phi(x)$ in the class under consideration and for some $\phi(x)$ a strong inequality holds.

with a strict inequality for some value x_0.

Condition (4) can be rewritten as:

$$G_2(x/t_1) = F_2(x/t_1) + \delta(x/t_1)$$

where $\delta(x/t_1) \geq 0$ and for some value x_0/t_{1_0}, $\delta(x_0/t_{1_0}) > 0$

Substituting this result in (7), we have to prove that,

$$(8)\quad \int_0^\infty F_2(x/t_1)[f_1(t_1) - g_1(t_1)]dt_1 - \int_0^\infty \delta(x/t_1)g_1(t_1)dt_1 \leq 0$$

Since $\delta(x/t_1)$ and $g_1(t_1)$ are nonnegative, it is enough to show that:

$$(9)\quad \int_0^\infty F_2(x/t_1)[f_1(t_1) - g_1(t_1)]dt_1 \leq 0$$

Integrating (9) by parts, we get:

$$(10)\quad \int_0^\infty F_2(x/t_1)[f_1(t_1) - g_1(t_1)]dt_1 = \left\{F_2(x/t_1)(F_1(t_1) - G_1(t_1))\right\}_0^\infty - \int_0^\infty [F_1(t_1) - G_1(t_1)]\frac{\partial F_2(x/t_1)}{\partial t_1}dt_1 \leq 0$$

Recalling that $F_1(\infty) = G_1(\infty) = 1$ and $G_1(0) = F_1(0) = 0$, the first term in the right side of (10) vanishes, and what is left to show is that the second term is nonpositive, i.e., that (11) holds

$$(11)\quad -\int_0^\infty [F_1(t_1) - G_1(t_1)]\frac{\partial F_2(x/t_1)}{\partial t_1}dt_1 = \int_0^\infty \left\{[F_1(t_1) - G_1(t_1)]f_2(x/t_1)x/t_1^2\right\}dt_1 \leq 0$$

The last term is nonpositive since, $f_2(x/t_1) \geq 0$, $x/t_1^2 \geq 0$, and by equation (3), $[F_1(t_1) - G_1(t_1)] \leq 0$.

Notice, also, that $\delta(x_0/t_{1_0}) > 0$ for some value (x_0/t_{1_0}), and hence there is a strict inequality in (7) at least for one value. Thus, $F(x) \leq G(x)$ and $F(x_0) < G(x_0)$ for some value x_0 which implies that the two-period distribution F dominates the two-period distribution G.

THEOREM 2: *Let F^n and G^n be the cumulative distributions of two n-period risks (note that the superscript respresents the number of periods which the cumulative distributions represent). A sufficient condition for F^nDG^n for every nondecreasing utility function is $F_i(x_i) \leq G_i(x_i)$ for all values of x_i, and $F_i(x_{i_0}) < G_i(x_{i_0})$ for some value x_{i_0}, for $i = 1, 2, \ldots, n$*

In fact, only one strict inequality is sufficient to prove this theorem. However, to simplify, we shall not emphasize throughout the paper the need for a strong inequality.

PROOF:

The proof is by induction: For $n = 2$, $F_i(x_i) \leq G_i(x_i)$ $(i = 1, 2)$ implies that F^2 dominates G^2 (Theorem 1). Let us assume that Theorem 2 holds for $n-1$ periods, and prove that it also holds for n periods, i.e., we assume that:

$$F_i(x_i) \leq G_i(x_i)$$

$$(i = 1, 2, \ldots, n-1) \Rightarrow F^{n-1} \text{ dominates } G^{n-1}$$

We now have to show that $F_i(x_i) \leq G_i(x_i)$ $(i = 1, 2, \ldots, n)$ implies that F^n dominates G^n. Note that $F_i(x_i) \leq G_i(x_i)$ (for $i = 1, \ldots, n-1$) implies that F^{n-1} dominates G^{n-1} (by assumption) i.e., $F^{n-1}(\prod_{i=1}^{n-1} x_i) \leq G^{n-1}(\prod_{i=1}^{n-1} x_i)$ for all values $\prod_{i=1}^{n-1} x_i$. Since x_n and $\prod_{i=1}^{n-1} x_i$ are independent, and it is given that $F^{n-1} \leq G^{n-1}$ and $F_n \leq G_n$, one can again use Theorem 1 to prove that $F^n(\prod_{i=1}^n x_i) \leq G^n(\prod_{i=1}^n x_i)$ i.e., F^n dominates G^n.[9]

COROLLARY 1: *If, in addition to the assumption of independence, we also assume stationarity over time of the distributions under consideration, one may conclude that for any two horizons, n_1 and n_2 $(n_2 > n_1)$, the number of options in the efficient set which is appropriate to horizon n_2 is not larger than the number of options in the efficient set which is appropriate to horizon n_1, where the efficient sets are defined for all nondecreasing utility*

[9] Note that in Theorem 1 we did not assume stationarity over time of the distributions. The comparison of the pair (F^{n-1}, F_n) with the pair (G^{n-1}, G_n) does not violate the conditions under which Theorem 1 holds.

functions. This conclusion stems directly from Theorem 1.

Suppose we have two options, F and G. The stationarity assumption implies that, $F_1=F_2 \ldots =F_n$ and $G_1=G_2= \ldots G_n$. For the sake of simplicity, suppose that $n_1=1$ and $n_2=n$. If F_1DG_1, then, by the stationarity assumption, F_i also dominates G_i for all other periods $i=2, \ldots, n$.[10] Hence, by Theorem 1, F^n dominates G^n.

To sum up, an option which is eliminated from the one-period efficient set, is also eliminated from the n-period efficient set. Hence, the number of options in the efficient set of the long horizon cannot exceed the number of options in the efficient set of the short horizon.

It is interesting to note that one can find numerical examples for which the number of elements in the efficient set is strictly decreasing when the horizon increases. Consider the following two-period example, where $F_1=F_2$ and $G_1=G_2$.

Example 1

G_1 (or G_2)		F_1 (or F_2)	
Outcome	Probability	Outcome	Probability
1	1/4	2	1/2
4	3/4	10	1/2

Assuming independence over time, the two-period distributions F^2 and G^2 are:

G^2		F^2	
Outcome	Probability	Outcome	Probability
1	1/16	4	1/4
4	6/16	20	1/2
16	9/16	100	1/4

Since F_1 and G_1 (or F_2 and G_2) intersect, both of them are included in the one-period efficient set. But $F^2(x) \leq G^2(x)$ for every x (with a strict inequality for some values) and, hence, F^2DG^2. This numerical example shows that portfolios which are not eliminated from the one-period efficient set might be eliminated from the multi-period efficient set.[11]

II. Multi-period Dominance in the Case of Risk Aversion

It has been shown that for the one-period investment case, a necessary and sufficient condition for a risk with cumulative probability distribution function F_1 to dominate one with $G_1(F_1DG_1)$ as its cumulative distribution function, for all nondecreasing *concave* utility functions, is:

$$\int_{-\infty}^{x} [G_1(t) - F_1(t)]dt \geq 0$$

for every x, and $G_1 \neq F_1$ for some x_0, where the subscript 1 indicates the distribution for period one. (See articles by Hadar and Russell, Hanoch and Levy, and Rothschild and Stiglitz.) We shall now prove that if F_1DG_1 and F_2DG_2, then, F dominates G, where F and G are the two-period distributions

Before proceeding to state and prove a theorem for the multiperiod risk aversion case we need the following:

LEMMA: *Let $T(x, t_1)=\int_0^x F(t/t_1)dt$, where F is some (cumulative) distribution function. Then,*

$$\frac{\partial T(x, t_1)}{\partial t_1} = T'(x, t_1) \leq 0 \quad \textit{and}$$

$$\frac{\partial^2 T(x, t_1)}{(\partial t_1)^2} = T''(x, t_1) \geq 0$$

PROOF:

$$(12) \qquad T'(x, t_1) = \frac{\partial \int_0^x F(t/t_1)dt}{\partial t_1} = \int_0^x \left(\frac{\partial F(t/t_1)}{\partial t_1}\right) dt$$

Let $f(t/t_1)$ be the density function of $F(t/t_1)$. Then,

[10] The stationarity assumption implies that the number of elements in the efficient sets constructed for each single period (e.g., year) is the same.

[11] The numerical example confirms that the conditions for dominance given in Theorem 1 are sufficient, but not necessary.

$$T'(x, t_1) = -\int_0^x [f(t/t_1)t/t_1^2]dt \leq 0$$

since the integrand is always nonnegative.

The proof that $T''(x, t_1) \geq 0$ is somewhat more involved:

$$T''(x, t_1) = -\frac{\partial \int_0^x [f(t/t_1)t/t_1^2]dt}{\partial t_1}$$

$$= -\int_0^x \frac{\partial[f(t/t_1)t/t_1^2]}{\partial t_1} dt$$

Hence,

$$\text{(13)} \quad T''(x, t_1) = -\left[\int_0^x f'(t/t_1)(-t/t_1^2)(t/t_1^2)dt + \int_0^x f(t/t_1)(-2t/t_1^3)dt\right]$$

Let us expand the first term on the right side of (13):

$$\int_0^x f'(t/t_1)\cdot(t^2/t_1^4)dt = \int_0^x [f'(t/t_1)1/t_1\cdot t^2/t_1^3]dt$$

Integrating by parts (with respect to x), we get:

$$\text{(14)} \quad \int_0^x [f'(t/t_1)(1/t_1)\cdot t^2/t_1^3]dt$$

$$= \{[f(t/t_1)t^2/t_1^3]\}_0^x - \int_0^x f(t/t_1)2t/t_1^3 dt$$

$$= f(x/t_1)x^2/t_1^3 - \int_0^x f(t/t_1)2t/t_1^3 dt$$

Substituting these results in (13), we get:

$$\text{(15)} \quad T''(x, t_1) = f(x/t_1)x^2/t_1^3 \geq 0$$

We can now prove the following theorem:

THEROEM 3: *Let F and G be the cumulative distributions for the two-period horizon of two alternative risks. A sufficient condition for FDG, for every nondecreasing concave utility function* ($\phi'(x) \geq 0$, $\phi''(x) \leq 0$) is:

$$\text{(16)} \quad \int_0^{x_i} [G_i(t_i) - F_i(t_i)]dt_i \geq 0 \quad (i = 1, 2)$$

for every value x_i, with a strict inequality for at least one value.

PROOF:

We have to prove that (17) holds:

$$\text{(17)} \quad \int_0^x [G(t) - F(t)]dt \geq 0$$

(with a strict inequality for some value x_0). Using (5) and (6), equation (17) can be rewritten:

$$\text{(18)} \quad \int_0^x \int_0^\infty G_2(t/t_1)g_1(t_1)dt_1 dt \geq \int_0^x \int_0^\infty F_2(t/t_1)f_1(t_1)dt_1 dt$$

By condition (16), for the second-period distribution we have:

$$\text{(19)} \quad \int_0^x G_2(t/t_1)dt = \int_0^x F_2(t/t_1)dt + \delta(x/t_1)$$

where $\delta(x/t_1) \geq 0$ and $\delta(x_0/t_{1_0}) > 0$ for at least one value (x_0/t_{1_0}). Substituting (19) in (18), we obtain:

$$\text{(20)} \quad \int_0^\infty ([g_1(t_1) - f_1(t_1)] \int_0^x F_2(t/t_1)dt)dt_1 + \int_0^\infty g_1(t_1)\delta(x/t_1)dt_1 \geq 0$$

Since the second term is nonnegative, it will suffice to prove that the first term in (20) is nonnegative.

Integrating the first term in (20) by parts, with respect to t_1, we obtain:

$$\text{(21)} \quad \left\{[G_1(t_1) - F_1(t_1)] \int_0^x F_2(t/t_1)dt\right\}_0^\infty$$

$$-\int_0^\infty [(G_1(t_1)-F_1(t_1)] \frac{\partial \int_0^x F_2(t/t_1)dt}{\partial t_1} dt_1 \geq 0$$

Since the first term equals zero, and $\int_0^{x_1} F_2(t/t_2)dt \equiv T(x, t_1)$ (by definition), it remains to prove that the following term is nonnegative.

$$(22) \quad \int_0^\infty \{[G_1(t_1) - F_1(t_1)]\} \left(-\frac{\partial T(x, t_1)}{\partial t_1}\right) dt_1 \geq 0$$

Note that $\int_0^{x_1}[G_1(t_1)-F_1(t_1)]dt_1 \geq 0$ for every x_1 (by (16)), and $-T(x, t_1)$ is nondecreasing concave (utility) function in t_1 (by the Lemma). Applying (2′) to this case we get,

$$(23) \quad \int_0^{x_1} [G_1(t_1) - F_1(t_1)]dt_1 \geq 0$$

$$\Rightarrow \int_0^\infty [G_1(t_1) - F_1(t_1)]\left(-\frac{\partial T(x, t_1)}{\partial t_1}\right)dt_1 \geq 0$$

Hence inequality (23) holds.

We also have in (20) at least one strict inequality, since for some value x_0/t_{1_0}, $\delta(x_0/t_{1_0}) > 0$. Hence, FDG.

THEOREM 4: *Let F^n and G^n be the cumulative distributions of two n-period risks. A sufficient condition for F^nDG^n for all nondecreasing concave utility functions is $\int_0^{x_i}[G_i(t_i) - F_i(t_i)]dt_i \geq 0$ for every x_i (with a strict inequality for some x_{i_0}), where $i=1, 2, \ldots, n$.*

PROOF:

The proof is by induction and similar to that given in Theorem 2. For $n=2$, it has been proved in Theorem 3 that $\int_0^{x_i}[G_i(t_i) - F_i(t_i)]dt_i \geq 0$ (for every x_i where $i=1, 2$) implies that F^2 dominates G^2, for all risk averters. Assume, that the statement of the theorem holds for $n-1$ period, i.e., $\int_0^{x_i}[G_i(t_i) - F_i(t_i)]dt_i \geq 0$ (for every x_i where $i=1, 2, \ldots, n-1$) implies that F^{n-1} dominates G^{n-1}. We have to prove that the theorem also holds for n-periods. This is straightforward; since F^{n-1} dominates G^{n-1}, one can conclude that

$$\int_{-\infty}^{\prod_{i=1}^{n-1} x_i} [G^{n-1}(t) - F^{n-1}(t)]dt \geq 0 \quad \text{for every } \prod_{i=1}^{n-1} x_i$$

Since by assumption of the theorem,

$$\int_{-\infty}^{x_n} [G_n(t) - F_n(t)]dt \geq 0$$

for every x_n, we may again employ Theorem 3[12] and prove that

$$\int_{-\infty}^{\prod_{i=1}^{n} x_i} [G^n(t) - F^n(t)]dt \geq 0$$

for all values $\prod_{i=1}^n x_i$, i.e., F^n dominates G^n for all risk averters.

COROLLARY 2 *If we are prepared to assume stationarity over time, in addition to independence of the returns, i.e., $F_1=F_2= \ldots =F_n$ and $G_1=G_2= \ldots =G_n$, we may conclude that the number of elements in the efficient set which is constructed for all risk averters does not increase when the investment horizon increases. This conclusion follows from Theorem 3.*

Suppose that in period 1, F_1 dominates G_1, i.e., $\int_0^{x_1}[G_1(t)-F_1(t)]dt \geq 0$ for all values x_1, then, by the stationarity assumption, F_i dominates G_i for all other periods i ($i=1, 2, \ldots, n$), and by Theorem 3, F^n dominates G^n. In other words, any option which is eliminated from the risk averters' one-period efficient set is also eliminated from the n-period efficient set. The efficient set in each single period is identical, and the n-period efficient set is no greater than the single period efficient set. Again, as in the previous case, we can find examples where the efficient set is strictly decreasing when

[12] Note again that, by assumption, x_n and $\prod_{i=1}^{n-1} x_i$ are independent, i.e., by looking at the results of the first $n-1$ periods one cannot improve prediction with respect to the nth period.

the investment horizon increases.[13] We shall again use Example 1 above to illustrate this argument: F_1 does not dominate G_1 (i.e., $F_1 D G_1$) for all risk averters since,

$$\int_0^4 [G_1(t_1) - F_1(t_1)]dt_1 = -1/4 < 0$$

But, also, G_1 does not dominate F_1

$$\int_0^2 [F_1(t_1) - G_1(t_1)]dt_1 = -1/4 < 0$$

Hence, F_1 and G_1 are included in the one-period efficient set. Assuming stationarity over time $F_1 = F_2$, $G_1 = G_2$, and hence also $F_2 D G_2$, $G_2 D F_2$, which means that F_2 and G_2 are included in the second period efficient set.

Looking back at Example 1, we can see that, in the two-period horizon, $F^2(x) \leq G^2(x)$, for every x and for some value x a strict inequality holds. Consequently $\int_0^x [G^2(t) - F^2(t)dt] \geq 0$ (with a strict inequality for some value x_0) and, hence, F^2 dominates G^2. Therefore, in this example the risk averters' efficient set decreases when the investment horizon increases.

IV. Concluding Remarks

This study investigated the role of the investment horizon in determining the efficient set of portfolios. We found that, unlike the one-period case, the efficiency criteria for the multi-period case are sufficient but not necessary for dominance. If a portfolio is eliminated from each single period efficient set it will also be eliminated from the multi-period efficient set, but the inclusion of a portfolio in *each* single period efficient set does not guarantee that this portfolio will be included in the multi-period efficient set.

Thus, an investment consultant who screens all the available portfolios should construct the efficient set for each group of investors according to their investment horizon. However, the consultant may construct the efficient set for the shortest relevant horizon, knowing that the efficient set which is appropriate for longer horizons must be a subset of (or identical to) the efficient set which has been obtained for the short horizon. Nevertheless, one should keep in mind that the suggested procedure is valid only under the case in which probability functions are stationary over time. Otherwise, the consultant can not limit his attention only to the first period distributions.

The magnitude of the decrease in the efficient set resulting from an increase in the investment horizon is left to be investigated either empirically or by simulation.

[13] This means that the longer the horizon the smaller the efficient set. Similar results have been obtained by Nils Hakansson, who assumes that the objective function of the investors is to maximize the geometric average return over time. In Hakansson's analysis, when $n \to \infty$, the efficient set includes only one portfolio, which is also the optimal one. It is of interest to note that Menachem Yaari, who analyzes the individual's multi-period investment-consumption decision, obtains similar results: the longer the horizon, the more certain the optimal consumption and when $n \to \infty$, the individual investment-consumption decisions are determined as with certainty.

Spot Speculation, Forward Speculation, and Arbitrage: Comment

By HOUSTON H. STOKES*

In his famous article in *Staff Papers*, S. C. Tsiang showed that the return to spot speculation was equal to the return to forward speculation plus the return to interest arbitrage. This note argues that this result is only strictly true in all cases if there is no government (central bank) intervention in the forward market. In some situations of government intervention, Tsiang's result will not hold. As a consequence there is a loss of generality of Tsiang's analysis unless other conditions are specified. In this paper I develop the conditions to tell whether there is government intervention and if such intervention is sufficient to invalidate Tsiang's analysis.

I. The Model

If F is the 90-day forward rate,[1] S is the spot exchange rate, S^e the expected spot rate in 90 days, and i^f and i^d the foreign and domestic 90-day interest rates, respectively, then interest parity[2] implies

$$F(1 + i^f) = S(1 + i^d) \tag{1}$$

If

$$F^* \equiv \frac{S(1 + i^d)}{(1 + i^f)} \tag{2}$$

there will be an outflow (inflow) of funds from the domestic country if F is greater (less) than F^*. If C_{at} is defined as the desired stock of forward contracts held by arbitragers in period t, then[3]

$$C_{at} = \phi(F - F^*) \quad \text{where } \phi < 0 \tag{3}$$

Forward speculators will sell (buy) the foreign currency forward if F is greater (less) than S^e. If C_{st} is the desired stock of forward contracts held by forward speculators in period t then

$$C_{st} = \Psi(F - S^e) \quad \text{where } \Psi < 0 \tag{4}$$

Parity in the spot speculation market occurs when

$$S(1 + i^d) = S^e(1 + i^f) \tag{5}$$

From equations (5) and (2) we note that spot speculators will acquire the foreign (domestic) currency spot if S^e is greater (less) than F^*. If $C_{\hat{s}t}$ is the desired stock of the domestic currency held by spot speculators in period t then

$$C_{\hat{s}t} = Z(S^e - F^*) \quad \text{where } Z < 0 \tag{6}$$

We can plot equations (3) and (4) as the AA and SS curves where the intersection of SS and AA with the vertical axis is S^e and F^*, respectively. This has been done in Figures 1 and 2.[4] In the absence of governmental intervention $F^* \geq F \geq S^e$ (Figure 1) or $S^e \geq F \geq F^*$ (Figure 2). Since the return to

* Assistant professor of economics, University of Illinois at Chicago Circle. I am indebted to Robert Mundell, Harry Johnson, and other members of the University of Chicago International Trade Workshop. Zoran Hodjera of the IMF made many helpful suggestions on an earlier draft. An anonymous referee also contributed. Any remaining errors are my responsibility.

[1] All exchange rates are quoted as the domestic currency price of one unit of the foreign currency. Time subscripts are ignored.

[2] This interest parity condition, the usual one, is a simplified version of the one Tsiang uses. If one thinks in Tsiang's terms one can "adjust" the interest rates for the subjective marginal convenience yield. This simplification does not affect the analysis.

[3] If C_{at} is negative (positive) arbitragers have made an outflow (inflow).

[4] The graphical treatment of the model is based on B. Reading's work. This model is a simplified version of Tsiang's; I have used it in my 1972 article. If $\phi = -\infty$ then there is perfect capital mobility and the AA curve is perfectly elastic. Here arbitragers determine the forward rate. If $\Psi = -\infty$ then the SS curve is perfectly elastic and speculators determine the forward exchange rate. It is impossible for $\phi = -\infty$ and $\Psi = -\infty$ at the same time except in the trivial case where $S^e = F^*$ or the SS curve lies on top of the AA curve.

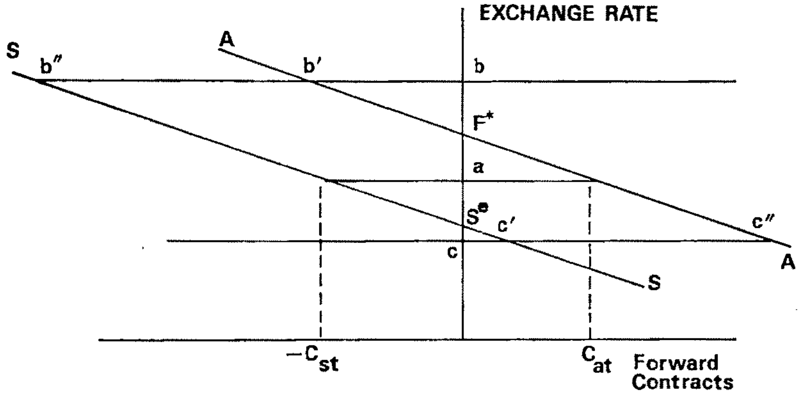

FIGURE 1. NOTE: a = NONINTERVENTION LEVEL OF F

forward speculation is ($|S^e-F|$), the return to interest arbitrage is ($|F^*-F|$) and the return to spot speculation is ($|S^e-F^*|$) it clearly follows that in the absence of governmental intervention in the forward exchange market, Tsiang is correct; the return to spot speculation is equal to the return to forward speculation plus the return to interest arbitrage. This reduces to

$$|S^e - F^*| = |S^e - F| + |F - F^*| \tag{7}$$

We note that in this case

$$|C_{st}| = |C_{at}| \tag{8}$$

If the government intervenes in the forward market it is possible to have[5] any of the following cases.

[5] In my 1972 paper, I developed conditions concerning the effectiveness of forward intervention. By differentiating (3) and (6) with respect to F we can derive an expression for the net flow of money to the domestic country (dM_d) due to forward intervention. This reduces to

$$dM_d = dF\left[\frac{\partial S^e}{\partial F}Z + \phi\right] \quad \text{where} \quad \phi \neq -\infty$$

and

$$dM_d = dI\left[\frac{\partial S^e}{\partial F}Z + 1\right] \quad \text{where} \quad \phi = -\infty$$

and I = the dollar amount of forward contracts of the foreign currency sold by the central bank. This analysis builds on the effect of forward intervention on the position of the AA and SS schedules mentioned briefly by Tsiang but not worked out.

$$F \geq F^* \geq S^e \tag{9}$$

$$F^* \geq S^e \geq F \tag{10}$$

$$F \geq S^e \geq F^* \tag{11}$$

$$S^e \geq F^* \geq F \tag{12}$$

In all these cases, Tsiang's result does not hold. Equation (9) represents the government bidding the forward rate up to b starting from an initial situation represented by point a in Figure 1. The government has bought $bb'+bb''$ forward contracts from the arbitragers and forward speculators, respectively. Since F is now no longer between F^* and S^e, Tsiang's statement that the return to spot speculation $|S^e-F^*|$ is equal to the return to forward speculation $|S^e-F|$ plus the return to arbitrage $|F-F^*|$ is not correct. In this situation the return to forward speculation $|F-S^e|$ is equal to the return on arbitrage $|F-F^*|$ plus the return to spot speculation $|S^e-F^*|$.

In equation (10) the government starting from initial equilibrium in Figure 1 has sold contracts to the arbitragers and forward speculators driving the forward rate to c. Total government sales of forward contracts are equal to $cc'+cc''$. Here again Tsiang's proof does not hold. In this situation the return to arbitrage $|F-F^*|$ is equal to the return to spot speculation $|S^e-F^*|$ plus the return to forward speculation $|S^e-F|$.

In equation (11) the government starting

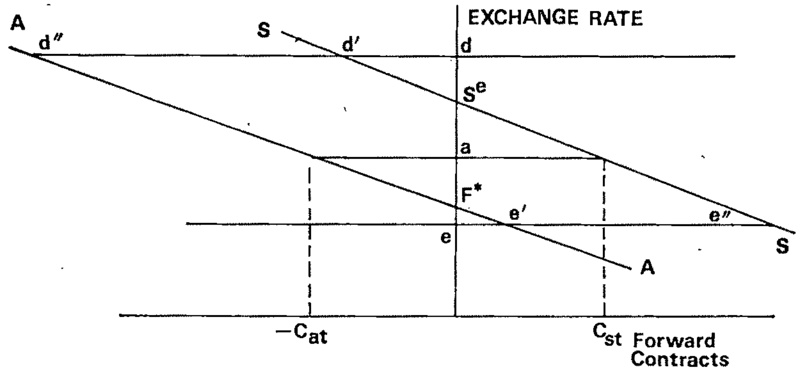

FIGURE 2. NOTE: a=NONINTERVENTION LEVEL OF F

from an initial equilibrium at point a in Figure 2 has bid the forward rate up to d by buying dd' from the forward speculators and dd'' from the arbitragers. Tsiang's proof no longer holds. We find that the return to arbitrage $|F-F^*|$ is equal to the return to spot speculation $|S^e-F^*|$ plus the return to forward speculation $|S^e-F|$.

In equation (12) the government has intervened to disturb the initial equilibrium represented by Figure 2 to push the forward rate down to e by selling ee' to the arbitragers and ee'' to the forward speculators. Here the return to forward speculation $|S^e-F|$ is equal to the return to spot speculation $|S^e-F^*|$ plus the return to arbitrage $|F-F^*|$.

Summarizing: In equations (9) and (12) instead of Tsiang's result, we find that the return to forward speculation is equal to the return to interest arbitrage plus the return to spot speculation. In equations (10) and (11), the return to interest arbitrage is equal to the return to spot speculation plus the return to forward speculation. These results are not surprising since if equation (9) represents the domestic country, equation (12) looks at the same situation from the point of view of the foreign country. Equations (10) and (11) are similarly related.

In short, only when

$$F^* \geq F \geq S^e \tag{13}$$

or

$$S^e \geq F \geq F^* \tag{14}$$

does Tsiang's result hold.

Equation (13) or (14) will hold if

$$|C_{at}| = |C_{st}| \tag{8}$$

and

$$C_{at} \neq C_{st} \tag{15}$$

If equation (8) and (15) do not hold we know there is government intervention.

Equation (13) and (14) can hold if $|C_{at}| \neq |C_{st}|$ if the government intervention has not driven the forward rate outside the band of spot speculation profitability, i.e., if C_{st} and C_{at} are not the same sign.[6]

The above findings are very important since Tsiang notes:

> . . . a speculator who speculates on the spot exchange market may, in fact, be regarded as acting implicitly in the combined capacity of an interest arbitrager and a forward exchange speculator . . . the tentative assumption stated above that all speculation in foreign exchange is carried on in the forward market, does not impair the generality of our analysis as long as speculators who in effect speculate in the spot market are treated according to their dual capacity, namely, first as interest arbitragers and then as speculators in forward exchange. [p. 92]

[6] Equation (15) is necessary if we are to take into consideration the possibility of an intersection of the AA and SS curves. In such a situation intervention could drive the forward rate to a position where equation (8) holds but where neither equation (13) or (14) is satisfied.

My paper has questioned Tsiang's basic assumption. I have shown that although Tsiang's analysis holds in all cases of nonintervention it holds with intervention only if equation (13) or (14) are met. If intervention causes equations (9), (10), (11), or (12) to hold, Tsiang's results lose generality. The most likely possibility would be a situation such as equation (12) where the government in response to a rapidly rising expected spot rate is pushing the forward rate down. This appeared to be the case of the United Kingdom in 1967 where during the crisis prior to the devaluation, the interest arbitragers were coming to the United Kingdom while the speculators were leaving. In short, this analysis suggests that for empirical work Tsiang's model must be used with caution since in the last decade prolonged periods of nonintervention have been the exception rather than the rule.

Spot Speculation, Forward Speculation, and Arbitrage: A Clarification and Reply

By S. C. TSIANG*

Houston Stokes' comment on my paper seems to be based on a misinterpretation of a passage of my 1959 article, which perhaps calls for further clarification. He asserts that I said somewhere in my paper that " . . . the return to spot speculation was equal to the return to forward speculation plus the return to interest arbitrage," (p. 996) but he does not bother to point out where I am supposed to have said this.

Searching through that article, which I wrote fourteen years ago, however, I could not find any sentence to that effect. What I said there in this connection was the following:

> Thus a speculator who speculates on the spot exchange market may, in fact, be regarded as acting implicitly in the combined capacity of an interest arbitrager and a forward exchange speculator. If he speculates by buying spot foreign exchange (instead of buying forward exchange), what he is doing is in fact equivalent to acting first as an interest arbitrager in buying spot exchange against a sale of an equal amount of forward exchange, and then as a forward speculator in buying the forward exchange from himself (in the former capacity) in the expectation that the future spot rate will rise higher than the current forward rate and yield him a pure speculative gain. If he speculates by selling spot exchange (instead of forward exchange), he is in fact acting first as an interest arbitrager in selling spot exchange against an equal amount of forward purchase, and then as a forward speculator in selling the forward exchange to himself in the former capacity in the expectation that the future spot rate will turn out to be lower than the current forward rate. [p. 92]

This statement is tautologically always true, even though the statement which Stokes attributed to me may not always be true.

There are no difficulties in the first two cases which he depicted in Figure 1 and Figure 2, i.e., $F^*>F>S^e$ and $S^e>F>F^*$, where F is forward exchange rate, $F^*=S(1+i^d)/(1+i^f)$ is the forward rate that would correspond to the interest parity (S being defined as the current spot rate and i^d and i^f the domestic and foreign interest rates, respectively), and S^e is the speculators' expected future spot rate. Stokes thinks that in the absence of government intervention, these are the only cases possible. This is open to question, but I shall postpone its discussion until later. In four other possible cases, he claims that I was wrong. For instance let us take the case $F>F^*>S^e$, i.e., his inequality (9).

In this case arbitragers would presumably hold spot foreign exchange and cover the holdings by selling equal amount forward. The profit of arbitrage per unit of foreign exchange would be $F-F^*$ if we neglect the convenience yields of spot funds on hand. The spot speculator would go short on spot exchange and expect to make the profit of F^*-S^e per unit of foreign exchange. The forward speculator would go short on forward exchange and expect to make the profit of $F-S^e$ per unit. Thus obviously the return to spot speculation is not equal to the return to forward speculation plus that to covered interest arbitrage. Rather it is the difference between the return to forward speculation and that to covered interest arbitrage. Therefore, he claims that I am wrong.

However, if he had read me more carefully, he should have seen that what is said in the quotation above is literally correct even in this anomalous case. For what I said was that " . . . if he (the speculator) specu-

* Cornell University.

lates by selling spot exchange, he is in fact acting first as an interest arbitrager in *selling* spot exchange against an equal amount of forward *purchase*, and then as a forward speculator in selling the forward exchange to himself . . . " It is clear from this sentence, that speculative *selling* of spot foreign exchange implies an arbitrage operation of *selling* spot covered by *buying* forward and then a speculative sale of forward exchange. In this anomalous case, however, the implied arbitrage operation in the direction I specified would incur a loss of (F^*-F). So the spot speculator's expected return from his spot selling is equal to the expected return to forward speculative selling minus the loss from the implied arbitrage operation. The arithmetic would then come out exactly right. Stokes' difficulty arises because he misinterprets my statement to mean that a spot speculator's expected return is equal to the expected return to forward speculation plus the return to interest arbitrage in whichever direction that is profitable at the time. Had he read my paper more carefully, he would have noticed that the arbitrage operation and accompanying forward speculation implied in a spot speculative sale (or purchase) should be in the specific directions clearly specified in the above paragraph, not just any pair of such operations in the directions that is profitable under the circumstances.

All the four cases in which he claims that he has caught me wrong can be explained in this way.

Stokes might perhaps shift his ground of criticism and go on to protest that if I claim my theory to be general, how can I assume that the spot speculators would implicitly do obviously irrational things, such as arbitraging in a direction opposite to what the interest parity and forward premium would indicate, or selling forward exchange for speculation when his own expected future spot rate is higher than the forward rate. The answer to this paradoxical question is that in all those four anomalous cases, it is in fact irrational for any one to undertake spot speculation. The fact that when spot speculation is decomposed into two implicit actions, one of these would obviously be irrational, merely reflects the inherent irrationality of such activity in those cases. For instance, in the case of his (9), $F>F^*>S^e$, the speculator who sells spot is obviously acting irrationally if he has equal access to the forward market as I assumed. For why should any one incur additional net interest cost in selling spot forward exchange in order to speculate, if he can sell forward exchange and expect to make a greater profit while running exactly the same risk arising from the uncertainty of expected future rate.

Readers with patience can easily reason out why in the other three anomalous cases also, spot speculation would itself be an irrational behavior. To decompose spot speculation into two implicit component acts, one of which is in the irrational direction, does not mean that we are imputing some irrationality upon a rational behavior. It merely brings out in stronger relief the inherent irrationality of spot speculation under those circumstances.

The reason why I wanted to subsume spot speculation under forward speculation and covered interest arbitrage is to simplify the theory of the joint determination of forward and spot exchange rates such that these rates can be said to be determined by actions of only three groups of participants: forward speculators, arbitragers, and commercial coverers, apart from government authorities who might intervene from time to time. Reviewing this theory after the lapse of fourteen years, it is gratifying to find that this theory is indeed quite general as I claimed then. For in the two normal cases, spot speculation can certainly be split into two implicit activities, covered arbitrage and forward speculation, each following its own rational principles of behavior. In the four anomalous cases that Stokes listed, spot speculation is an irrational behavior and can therefore be ruled out.

Having answered Stokes' criticism, it is my turn to offer him some comments in return. Stokes thinks that in the absence of governmental intervention the only cases possible are the two normal ones, i.e., $F^*>F>S^e$ and $S^e>F>F^*$. No explicit reason is given for

this, but one might perhaps guess that the reason at the back of his mind is that he somehow regards that without governmental intervention his equation (8) would hold, i.e.,

$$|C_{st}| = |C_{at}|$$

by which he probably meant that the desired stock of forward contracts held by forward speculators must equal the desired stock of forward contracts held by arbitragers in the opposite direction, i.e., $C_{st} = -C_{at}$.

Why should this be true is a mystery to me. Certainly my theory would not lead to such a conclusion at all. Stokes apparently thought that, without government intervention, forward speculators and arbitragers would be the only groups of operators on the forward exchange market, so that the demand of the one must be matched by the supply of the other.

This is patently not true; for he has left out a most important group of operators on the forward market, viz., traders seeking covering for their foreign exchange commitments. The chief social function of a forward exchange market is essentially to provide hedging or covering to traders. If traders do not deal in forward exchange at all, forward exchange market would lose its main *raison d'être*. When commercial coverers operate in forward market, there is no reason why Stokes' equation (8), or rather $C_{st} = -C_{at}$, should hold at all. I cannot see any reason why Stokes should abandon my diagram 1 on page 96 in favor of his grossly simplified and incomplete diagram to show the forces at play on the forward exchange market and the determination of the forward rate. Had he used my diagram, he would see that it is not impossible to have, say, a situation like (10) $F^* > S^e > F$, without any government intervention at all. As illustrated in Figure 1, there might be an excess supply of forward exchange on the part of commercial coverer (because of an export surplus). The excess supply may be absorbed by both the arbitragers and the speculators who for some reasons or other might expect only a mild appreciation. Thus the export surplus AB, which, under the assumption that traders cover all their trade commitments, would coincide with the excess supply of forward exchange on the part of commercial traders, is divided between forward speculators, who absorb $AC = FD$, and the interest arbitragers, who absorb $CB = EF$.

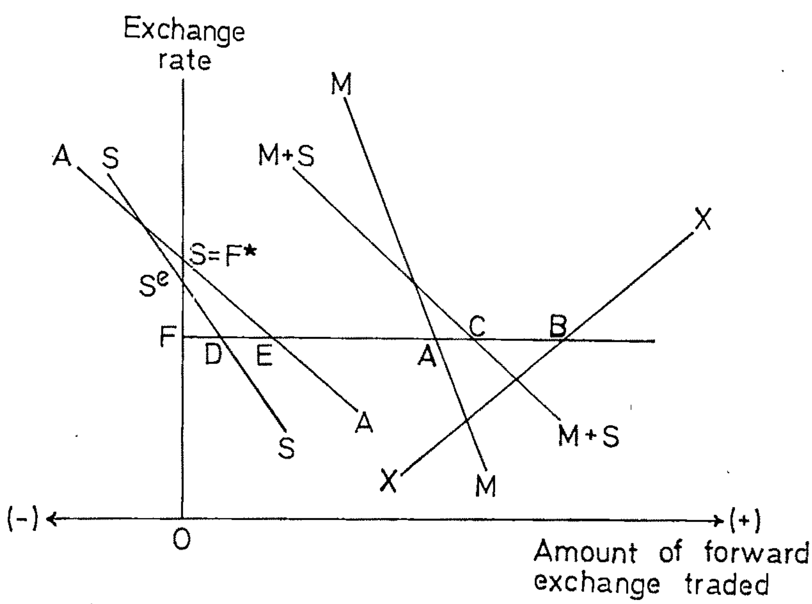

FIGURE 1

In this case, the generality of my theory still stands; viz., that both the forward and the spot rates of exchange can be said to be determined by the actions of three groups of participants: the commercial coverers, the arbitragers, and the forward speculators. For in this case, spot speculation, which would occupy spot funds just as interest arbitrage, but which would yield a return that is not only uncertain and risky but also expected to be smaller than the sure return of interest arbitrage, is certainly irrational and therefore can be ignored.

Pitfalls in Financial Model Building: Comment

By KEVIN CLINTON*

Mark Ladenson's recent elaboration of the point made by William Brainard and James Tobin, that security demand functions must be consistent with the balance sheet constraint, overcomplicates a simple issue. Furthermore, the two contributions by Ladenson and by Brainard and Tobin, taken together, are incomplete and misleading in certain respects. This note gives a general statement of the conditions for exact exhaustion of the balance sheet constraint which includes the Brainard and Tobin and Ladenson conditions as special cases, using derivations that are much simpler than those in Ladenson's article.

The demand functions with which I am concerned are written as linear functions, homogeneous in net wealth, W. Where y_{it}^* is the desired amount of asset i at time t, these functions are

$$(1) \qquad \overset{*}{y}_{it} = \beta_i W_t + \sum_{k=1}^{K} \beta_{ik} x_{kt} W_t \qquad i = 1, 2, \ldots, n$$

In addition to wealth there are K explanatory variables x_{kt} (interest rates, income, and the like) for the n assets. The β's are relevant coefficients.

Assuming that there is a generalized stock adjustment mechanism at work with parameters $\alpha_{ij}(i, j=1, 2, \ldots, n)$ the asset demand functions become

$$(2) \quad \Delta y_{it} = \sum_j \alpha_{ij}(\overset{*}{y}_{jt} - y_{j,t-1}) + \gamma_i \Delta W_t$$

where Δ is the first difference operator and γ_i is a coefficient which determines the initial allocation of a change in wealth into the component assets. Substitute (1) into (2):

$$\begin{aligned}(3) \quad \Delta y_{it} &= \sum_j \alpha_{ij}\left(\beta_j W_t + \sum_{k=1}^{K} \beta_{jk} x_{kt} W_t - y_{j,t-1}\right) + \gamma_i \Delta W_t \\ &= \sum_j \alpha_{ij}\beta_j W_t + \sum_j \alpha_{ij} \sum_k \beta_{jk} x_{kt} W_t - \sum_j \alpha_{ij} y_{j,t-1} + \gamma_i \Delta W_t\end{aligned}$$

The restrictions on the static model (1) are that $\sum_i \beta_i = 1$ and $\sum_i \beta_{ik} = 0$ for all k. Assume that $\sum_i \alpha_{ij}$ is constant over j. Sum (3) over i taking the foregoing into account:

$$(4) \qquad \sum_i \Delta y_{it} = \sum_i \sum_j \alpha_{ij}\beta_j W_t - \sum_i \sum_j \alpha_{ij} y_{j,t-1} + \sum_i \gamma_i \Delta W_t$$

In view of the fact that $\sum_i y_{it} = W_t$, (4) can be rearranged into

$$(5) \quad W_t = \left(\sum_j \beta_j \sum_i \alpha_{ij} + \sum_i \gamma_i\right) W_t + \left(1 - \sum_i \alpha_{ij} - \sum_i \gamma_i\right) W_{t-1}$$

or

$$(6) \quad W_t = \left(\sum_i \alpha_{ij} + \sum_i \gamma_i\right) W_t + \left(1 - \sum_i \alpha_{ij} - \sum_i \gamma_i\right) W_{t-1}$$

It is therefore sufficient[1] for the equality in (4) to hold that

$$(7) \qquad \sum_i \alpha_{ij} = 1 - \sum_i \gamma_i \qquad \text{for all } j$$

* Department of banking and financial analysis, Bank of Canada, Ottawa.

[1] As Ladenson points out, only sufficiency is at stake in this discussion, despite Brainard's and Tobin's reference to necessity.

Brainard and Tobin set $\sum_i \gamma_i = 1$, so that $\sum_i \alpha_{ij} = 0$. Ladenson's additional restriction is to set $\sum_i \gamma_i = 0$, so that $\sum_i \alpha_{ij} = 1$. These two restrictions omit a number of admissible and interesting specifications. Consider, for example, the following system:[2]

$$(8) \quad \alpha_{ij} = \begin{cases} \alpha = 1 - \sum_i \gamma_i \neq 0, & \text{for } i = j \\ 0, & \text{for } i \neq j \end{cases}$$

This system is consistent with (7). In view of this consistency it is interesting to find that Brainard and Tobin write, "If no cross effects were allowed in the explicit equations of adjustment . . . , then the counterparts of all the own adjustment coefficients specified would be loaded into the implicit adjustment equation for [the asset omitted by Walras' law]".[3] That is, if a lagged dependent variable appears in one equation then it must appear in at least one other equation also to provide for maintenance of the balance sheet identity Well, I have just provided a counterexample: there are no cross effects ($\alpha_{ij} = 0$ for $i \neq j$) and there is no omitted equation.

If you want to avoid the pitfalls into which Brainard and Tobin stumbled, as well as the pitfalls which they found, you should mark them clearly. As a clear and simple warning of pitfalls in dynamic financial models, I offer conditions (7).

[2] A specification actually used in the econometric model *RDX2*.

[3] See p. 106. The phrase in brackets is mine.

Pitfalls in Financial Model Building: Reply and Some Further Extensions

By Mark L. Ladenson*

Kevin Clinton has provided an interesting counterexample to the verbal argument that the omission of cross-adjustment coefficients necessarily misspecifies the system of asset adjustment proposed by William Brainard and James Tobin.[1] However, Clinton's specification is not a counterexample to any of the formal propositions developed in my paper. As Clinton observes in a footnote, I dealt with two alternative sets of *sufficient* conditions for consistency of that system. He has presented a third alternative. All three of these alternatives are special cases of the complete set of *necessary and sufficient* conditions for consistency. I did not develop these latter conditions in my paper since, at the time I wrote it, I did not recognize their economic interpretation. This interpretation can now be provided. I therefore welcome the opportunity to develop the complete set of conditions. I will *derive* as one of these conditions the proposition that all columns of the adjustment coefficient matrix, A, have the same sum (i.e., $\sum_i \alpha_{ij}$ is constant for all j). This is a proposition which Clinton needs in order to rearrange his equation (4) into his equation (5), and which he simply *assumes*. More important, however, will be our discussion of the meaning of the conditions.

We begin with equation (11′) of my 1971 paper in this *Review:*

$$(11') \quad \Delta W_t = r'AB_1X_1W_t + r'ABX_tW_t - r'Ay_{t-1} + r'\gamma_{\Delta W}\Delta W_t$$

Since equation (2) of the paper, $r'y_t = W_t$, holds identically in all time periods, and since $W_t \equiv W_{t-1} + \Delta W_t$, it follows that:

$$W_t = r'y_{t-1} + \Delta W_t$$

We substitute this last identity into the first term on the right-hand side of (11′), recall that X_1 is identically equal to unity, and collect terms to get

$$(I - r'\gamma_{\Delta W} - r'AB_1)\Delta W_t - (r'AB)X_tW_t - (r'AB_1r' - r'A)y_{t-1} = 0$$

This last relation will be satisfied if, and only if,

$$(11''\text{a}) \quad (I - r'\gamma_{\Delta W} - r'AB_1) = 0$$

$$(11''\text{b}) \quad r'AB = 0$$

$$(11''\text{c}) \quad r'A(I_5 - B_1r') = 0$$

The set of equations (11″) constitutes the complete set of necessary and sufficient conditions for consistency of the Brainard-Tobin system. Taking these conditions in reverse order, we will discuss their meaning and their implications for Clinton's counterexample. The third of them, (11″c), is indeed the proposition merely assumed by him: all columns of the adjustment coefficient matrix must have the same sum. For Clinton's counterexample to satisfy the condition, the columns of A must all sum to zero or the elements of the vector B_1 must sum to unity. Since Clinton (following the derivation in my original paper) utilized the latter restric-

* Assistant professor of economics, Michigan State University. I am deeply indebted to my colleague Robert H. Rasche for invaluable aid in preparing this note. I must also acknowledge my continuing debt to Walter D. Fisher, although I have not discussed the note with him. I, of course, accept all responsibility for errors.

[1] Clinton's specification that the change in each asset depends only on an own-adjustment coefficient multiplied by the gap between desired and actual values of that asset plus a coefficient multiplied by the total change in wealth has been previously proposed by Gregory Chow. Clinton has shown that the balance sheet restrictions imply that in Chow's specification all own-adjustment coefficients must be equal to each other. It should also be noted that the ordinary least squares estimates of each equation will not satisfy this restriction. One would probably want to use the estimation method devised by Arnold Zellner, though allowance would have to be made for the fact that the errors add to zero across equations for each observation.

tion in the course of his work, the counterexample satisfies this condition.

The elements of the matrix AB are impact multipliers. They give the impact effect on the assets (*ceteris paribus*) of changes in the exogenous variables other than wealth (interest rates and income). Equation (11″b) asserts that each column of this matrix must be equal to zero. That is, the impact effect of any interest rate or income change summed over all assets must be zero. For Clinton's counterexample to satisfy the condition, the columns of A must sum to zero or the columns of the matrix of structural coefficients, B, must sum to zero. Since Clinton (following the derivation in my original paper) utilized the latter restriction in the course of his work, his counterexample satisfies this condition.

Equation (11″a) deals with coefficients which give the effect of a change in net worth on the assets. These are the elements of the vector $\gamma_{\Delta W}$ and of the vector AB_1. It will be recalled that the elements of the former vector are the coefficients of the variable ΔW, and the elements of the latter vector are the coefficients of the variable W. Thus, in reduced form, the latter vector was named γ_1. Since its elements are the product of adjustment coefficients and structural coefficients they are impact multipliers. The influence of changes in wealth on the asset adjustment process is represented by the elements of both vectors. Equation (11″a) states that the sum of these influences must be unity; that the proportions in which a change in wealth is distributed across the portfolio add to 100 percent.

Unfortunately, as I noted in my paper, the complete system of adjustment equations cannot be estimated since an exact linear relation, $W_t = r'y_{t-1} + \Delta W_t$, prevails between the variables for all possible observations. As a result, if we wish to retain the symmetry of the matrix of adjustment coefficients we are not able to identify the elements of the vectors γ_1 and $\gamma_{\Delta W}$. (Equations (13Ra) and (13Rb) of my paper.) I suggested that we could deal with this problem by assuming all the elements of γ_1, on the one hand, or of $\gamma_{\Delta W}$, on the other, are equal to zero.[2] Equation (11″a) tells us that if we utilize the first of these alternatives, the elements of $\gamma_{\Delta W}$ sum to one, and if we utilize the second, the elements of γ_1 sum to one. In the former case we are setting the value of the impact multipliers equal to zero; we are assuming that the complete effect of a change in wealth on assets is represented by the elements of $\gamma_{\Delta W}$. Since these are not multiplied by the adjustment coefficient matrix, this case, as noted in my paper, involves the assumption that the assets adjust instantaneously to a change in wealth. On the other hand, I argued that if we utilize the other alternative, we assume that such adjustment occurs with a distributed lag. This point should now be more apparent, as we now recognize the elements of γ_1 to be impact multipliers.

It is possible to say more about patterns of adjustment and the meaning of these coefficients. In the case in which we set the elements of $\gamma_{\Delta W}$ equal to zero, the entire effect on the assets of a change in wealth is represented by the elements of γ_1. Since these involve multiplying the structural coefficients, the elements of B_1, by the same adjustment coefficients involved in the matrix AB, we are assuming that the assets adjust to a change in wealth at the same speed with which they adjust to a change in one of the exogenous variables (interest rates or income). Equation (11″a) does not, of course, require all the elements of γ_1 or of $\gamma_{\Delta W}$ to be equal to zero. The sums of the elements of both vectors might be positive and, added together, equal to one. For example, in Clinton's specification the elements of γ_1 sum to α and those of $\gamma_{\Delta W}$ to $(1-\alpha)$. In fact, from a purely formal viewpoint, we cannot exclude the possibility that the sum of the elements of γ_1 is positive, that of $\gamma_{\Delta W}$ is *negative*, and the two sums, added together, equal one. What does it mean if the adjustment equation of one of the assets has positive coefficients on both the W and ΔW variables? We have just seen that the co-

[2] At this point in the paper I made an error which is corrected below.

efficient of W involves the same speed of adjustment to a wealth-induced portfolio disequilibrium as to an interest-rate-induced disequilibrium. If the coefficient on ΔW is also positive it means that the effect of a change in wealth on the asset adjustment process is reflected both in the elements of γ_1 (the coefficient of W) and in the elements of $\gamma_{\Delta W}$ (the coefficient of ΔW). Therefore the asset in question adjusts more quickly to a change in net worth than to a change in interest rates. In parallel fashion, if the coefficient on ΔW is negative it means that the asset in question adjusts less quickly to a change in net worth than to a change in interest rates. Unfortunately, while these statements can be made in principle, if we wish to retain the symmetry of the adjustment coefficient matrix, there is no way to estimate the separate elements of γ_1 and $\gamma_{\Delta W}$ other than to assume that one or the other of these vectors is the null vector.

I wish to conclude by correcting two errors in my original paper. The first was simply a matter of notation. For the sake of multiplying conformable matrices, equation (13Rb) of my paper should have appeared as

$$y_t = [\Gamma_{2,7},\ \Gamma_{8,12} - \gamma_{\Delta W} r',\ \gamma_1 + \gamma_{\Delta W}] \begin{bmatrix} X_t W_t \\ y_{t-1} \\ W_t \end{bmatrix} + V_t$$

The second error is more important and not so simple. In the second column on page 183 I wrote: "To assume that the elements of γ_1 are all equal to zero and all the elements of X_t are not constant over time implies that W_t does not enter equation system (1) as an isolated variable in one of the linear terms. This in turn implies there is no functional dependence of the elements of the vector of equilibrium values of assets and liabilities, y_i^*, on net worth, apart from a scale factor." In other words, to set the elements of γ_1 equal to zero is to set the elements of B_1 equal to zero in the relation:

$$\overset{*}{y_t} = (B_1 X_1 + B X_t) W_t$$

But this is not the case. The ith element of γ_1 is obtained by post-multiplying the ith row of the matrix A by the vector B_1 (whose elements, of course, sum to one). Thus, in addition to requiring that each column of A sum to zero, we require that each row of A be such that all such inner products sum to zero. We also note that even though the variable W does not appear in the equations, we can solve our estimate of A for an estimate of B_1 by rewriting equation (15a′). I wrote it in the paper as

$$\text{(15a}'\text{)} \qquad \begin{bmatrix} \hat{\Gamma}^a_{2,7} \\ 0 \end{bmatrix} = \begin{bmatrix} \hat{A}^a \\ r' \end{bmatrix} \hat{B}^a$$

where $\hat{\Gamma}^a_{2,7}$ was our estimate of the matrix AB, $\hat{A}^a$ our estimate of the matrix A, and the problem was to solve this system for $\hat{B}^a$ our estimate of B. We can rewrite this equation as:

$$\begin{bmatrix} 0 & \hat{\Gamma}^a_{2,7} \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} \hat{A}^a \\ r' \end{bmatrix} [\hat{B}^a_1 \hat{B}^a]$$

We have added a column to the matrix on the left and a column to the second matrix on the right[3] The additions merely state that each element of $\hat{A}^a\hat{B}^a_1$, our estimate of γ_1, equals zero, and that the elements of $\hat{B}^a_1$, our estimate of B_1, sum to unity. We can solve this system for $\hat{B}^a_1$ in the manner described in my paper for solving the system (15a′) for $\hat{B}^a$.

[3] It is instructive to compare this augmented version of equation (15a′) with my paper's equation (15b′) which referred to a system in which the elements of γ_1 were not constrained to zero, and the elements of $\hat{\gamma}_1$ are the regression coefficients of W.

$$\text{(15b}'\text{)} \qquad \begin{bmatrix} \hat{\gamma}_1 & \hat{\Gamma}^b_{2,7} \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} \hat{A}^b \\ r' \end{bmatrix} [\hat{B}^b_1 \hat{B}^b]$$

It is clear that the augmented version of (15a′) is the exact analogue of (15b′) for the case in which all the elements of γ_1 are constrained to zero.

G. Chow, "On the Long-Run and Short-Run

The Industrial Composition of U.S. Export and Subsidiary Sales to the Canadian Market: Note

By H. G. Baumann*

In a recent article in this *Review*, Thomas Horst has shown that for *U.S.* firms, exports (X) and subsidiary sales (P) represent alternative means of utilizing their technological superiority over Canadian competitors. Furthermore, he showed that the Canadian tariff and relative cost factors determined whether the *U.S.* advantage was exploited through exports *or* subsidiary sales. The purpose of this note is to present some additional empirical support for Horst's conclusions, and to indicate areas where further research is desirable.

In the equations estimated below, two measures which refer to the output rather than the input of the technological effort of industries are employed. The substitution of research and development ($R\&D$) expenditures by patents issued in industry i in Canada (PA) yields the following results:[1]

$$X_i = .049 + \underset{(1.54)}{175.37}\, PA_i \qquad R^2 = .16 \quad \text{d.o.f.} = 12 \tag{1}$$

$$P_i = .172 + \underset{(3.09)}{594.15}\, PA_i \qquad R^2 = .44 \quad \text{d.o.f.} = 12 \tag{2}$$

$$S_i = .222 + \underset{(3.50)}{759.52}\, PA_i \qquad R^2 = .51 \quad \text{d.o.f.} = 12 \tag{3}$$

This compares with Horst's results for the same sample of industries as follows:

$$X_i = .032 + \underset{(2.55)}{6.05}\, R\&D_i \qquad R^2 = .35 \quad \text{d.o.f.} = 12 \tag{4}$$

$$P_i = .190 + \underset{(4.67)}{13.51}\, R\&D_i \qquad R^2 = .41 \quad \text{d.o.f.} = 12 \tag{5}$$

$$S_i = .221 + \underset{(4.11)}{19.56}\, R\&D_i \qquad R^2 = .58 \quad \text{d.o.f.} = 12 \tag{6}$$

Therefore, it appears questionable that technological intensity as measured by patents can explain *U.S.* exports to Canada (the critical value for the t-statistic at the 5 percent level with 12 degrees of freedom is 1.78), but that patents do better (higher R^2) than $R\&D$ in explaining subsidiary production. However, the former result changes dramatically when the following *log* formulation is used:

$$ln\ X_i = 5.17 + \underset{(3.82)}{.940}\, ln\ PA_i \qquad R^2 = .55 \quad \text{d.o.f.} = 12 \tag{7}$$

This formulation has a higher R^2 than the equivalent equation with the *log* of $R\&D$ as the explanatory variable, and in general the log form gives a slightly better fit. When *both* patents and $R\&D$ are introduced as independent variables the variables fail to be significant thus indicating a multicollinearity problem. It appears then that patents and $R\&D$ can be used interchangeably as measures of technological intensity.

However, some observers feel that patents, like $R\&D$, are undesirable as proxies for technological intensity. For example, there may be a bias from one industry to the next in terms of the extent to which patent protection is sought. Fortunately, McGraw-Hill has undertaken a survey over a number of years which asks managers to estimate the amount of sales of "new" products at some date in the future. New products (NP) are defined as products which are not being sold at the time of the survey. For example, in

* Assistant professor of economics, University of Western Ontario. I would like to acknowledge the helpful comments of my colleague Don McFetridge. Ed Kolano performed the computations.

[1] Precise definitions and data sources for the variables are given in the Statistical Appendix: $S_i \equiv X_i + P_i$.

1965, managers in the machinery industry estimated that 23 percent of 1969 sales would consist of products not yet produced. When these data are employed the estimated equations are:

$$X_i = -.021 + .913\, NP_i \quad (8)$$
$$(2.86)$$
$$R^2 = .45 \quad \text{d.o.f.} = 10$$

$$P_i = .356 + .154\, NP_i \quad (9)$$
$$(.181)$$
$$R^2 = .003 \quad \text{d.o.f.} = 10$$

$$S_i = .335 + 1.07\, NP_i \quad (10)$$
$$(1.14)$$
$$R^2 = .12 \quad \text{d.o.f.} = 10$$

The export equation confirms that the United States tends to exploit her comparative advantage in producing new products. The results are better than when $R\&D$ is the explanatory variable, which is not surprising given that NP adjusts for the efficiency of the $R\&D$ effort to some extent. A second reason for the higher R^2 with NP may be that the *U.S.* comparative advantage is probably not entirely based on a technological advantage, narrowly defined, but also on general organizational, marketing, and financial skills which are more crucial for new as compared with old products.[2]

The three equations above taken together give some support for the product cycle theory pioneered by Raymond Vernon. Apparently there is a lag between the production and export of a new product from the United States and the production of that same product by *U.S.* subsidiaries in Canada. This would account for the fact that production of *U.S.* subsidiaries does not appear to be concentrated in industries where new products form a large proportion of total sales. (By the time that a product is manufactured in Canada, i.e., after the imitation lag, it is already in the growth or mature phase of the product cycle, and hence, NP fails to be significant.) A more appropriate variable for the second equation would probably be the percentage of production carried on with new *processes* in the various industries, but these data are not available.[3] However, it is possible to adjust the $R\&D$ variable by weighting it with the percentage of entrepreneurs who believe that technological breakthroughs will occur in processing within a particular industry. The following results were obtained from this exercise:

$$P_i = .185 + 35.4\, RDA_i \quad (11)$$
$$(2.80)$$
$$R^2 = .44 \quad \text{d.o.f.} = 10$$

In conclusion, our results confirm those of Horst with the additional refinement that the comparative advantage of *U.S.* exports is largely based on product innovating while the comparative advantage of *U.S.* subsidiaries may be based on process innovating.

Horst also explains the choice between *U.S.* exports and foreign subsidiary production. In the Canadian case, he finds that the higher the Canadian tariff (t) and the smaller the size of the Canadian market (Z), the larger will be the ratio of *U.S.* exports to subsidiary production for any given industry. Although Horst mentions real cost considerations other than economies of scale as determining the above choice, he does not introduce them into his equations. However, existing data make it possible to introduce the ratio of *U.S.* to Canadian wages per man-hour paid (WA). Horst's original results, and results with this additional explanatory variable are given below:

$$ln\left(\frac{X_i}{S_i}\right) = -.23 - 2.45\, ln\,(1 + t_i) \quad (12)$$
$$(3.23)$$
$$- 12.6\, Z_i$$
$$(3.24)$$
$$R^2 = .70 \quad \text{d.o.f.} = .15$$

[2] This point was already made by Horst, but the following empirical results may substantiate his statement. The advertising to sales ratio in *U.S.* industries fails to be significant when introduced as an explanatory variable into the above equations. This variable may be taken as a proxy for the degree of product differentiation, and old and new products may be highly differentiated, but the former do not require innovative talents either of the scientific or managerial type.

[3] In a recent paper, David Ault has shown that the export performance of the steel industries of a sample of countries can be explained by their use of different steelmaking processes. Of course, new products and processes may occur simultaneously, and therefore this distinction is not always valid. One example of the latter case has been studied by J. E. Tilton.

$$(13)\quad ln\left(\frac{X_i}{S_i}\right) = \underset{(4.42)}{5.62 - 2.72\, ln\,(1 + t_i)} - \underset{(5.86)}{19.2\, Z_i} - \underset{(3.84)}{.046\, WA_i}$$
$$R^2 = .87 \quad \text{d.o.f.} = 14$$

Obviously Horst is on the right track since the R^2 is raised from .70 to .87 and the wage variable has the right sign and is significant. However, the model is still not complete since the costs of raw material and manufactured inputs have been left out. Conceivably one might construct a variable of input costs based on *U.S.* and Canadian prices for the major or representative inputs of the industries in the sample, but this would be a major undertaking.

Statistical Appendix

Horst was kind enough to supply me with data on the first six variables defined below. I would like to thank Imre Bernolak of the Department of Industry, Trade, and Commerce, Ottawa, for helping with the data on wages and material costs in *U.S.* and Canadian industries. Data are for the year 1963.

$P_i \equiv$ Sales by *U.S.*-owned subsidiaries in Canada divided by total sales of all Canadian firms plus total Canadian imports for commodity i.

$X_i \equiv$ *U.S.* exports to Canada divided by total Canadian sales plus total Canadian imports of commodity i.

$S_i \equiv X_i + P_i$

$R\&D_i \equiv$ Company sponsored research and development expenditures divided by total sales for industry i in the United States.

$t_i \equiv$ Estimated nominal protection of the Canadian industry.

$Z_i \equiv$ Ratio of Canadian production plus imports divided by *U.S.* domestic production for industry i.

$PA_i \equiv$ Patents granted divided by total shipments of industry i in Canada. Data for patents are from O. J. Firestone. Shipments data are from Statistics Canada. Patents are classified into industries according to their end use. For comparison purposes it may have been desirable to use *U.S.* data. However, only 5.5 percent of patents granted in Canada have a local origin while 69.8 percent originate in the United States and 24.7 percent come from elsewhere (based on total patents granted 1957, 1960, 1963). In any case, when only patents granted to *U.S.* firms or individuals are included, the empirical results do not change. Nor do they change if three-year totals (1957+1960+1963) are used which indicates that the flow in one year does in fact reflect the stock as Horst assumes.

$NP_i \equiv$ Percent of 1969 sales consisting of products which were not produced in 1965. The source for these data is McGraw-Hill Economics Department. Ideally, the data should refer to 1963, but experimentation with data from more recent years did not lead to results different from those presented in the note.

$RDA_i \equiv (R\&D)_i x A_i$ where $A \equiv$ fraction of managers who believe that important breakthroughs will occur in processing as opposed to new products in industry i. The sources for the data are the same as those given for RD_i and NP_i above, respectively.

$WA_i \equiv$ *U.S.* wages per man-hour divided by Canadian wages per man-hour. Data for this variable are from Department of Industry, Trade, and Commerce, Ottawa. The data were converted from a three-digit basis to a two-digit basis by using employment figures as weights.

Lifetime Portfolio Selection in Continuous Time for a Multiplicative Class of Utility Functions

By GORDON PYE*

In a recent paper, Richard Meyer has studied the lifetime portfolio problem in continuous time for a multiplicative class of utility functions. Though obtaining a number of general characteristics of the optimal policy, he is able to obtain an analytic solution only for a special limiting case that corresponds to the additive family. The solution for this additive family is known from the independent work of Robert Merton, who, for continuous time, attacked this case directly. The continuous time case requires the assumption that the distribution of returns follow an infinitely divisible normal process. The discrete time case does not require this assumption. The additive family in discrete time has been studied by Edmund Phelps, Nils Hakansson, David Levhari and T. N. Srinivasan, and Paul Samuelson.

The purpose of this note is to point out that an analytic solution can be obtained for a subclass of the multiplicative family studied by Meyer. For discrete but not continuous time, I have given this solution in my 1972 paper. This solution differs significantly from that for the additive case in either discrete or continuous time. In the additive case, for a stationary distribution of returns, the proportion of wealth invested in risky securities doesn't change with age. This is not true for the solution in the multiplicative case. The proportion of wealth invested in risky securities increases or decreases with age as risk aversion is greater or less than that of the logarithmic utility function. The measure of risk aversion is the index of relative risk aversion developed by Kenneth Arrow and by John Pratt. If the logarithm may be thought of as the dividing line between optimists and pessimists, this result may be interpreted as follows. Optimists tend to gamble less as they grow older as they have less to gain, whereas pessimists gamble more as they have less to lose. Unlike the additive case, risk aversion in portfolio selection also depends on impatience in the multiplicative solution. Risk aversion in portfolio selection increases with impatience for optimists, while the reverse holds for pessimists. As the propensity to consume also depends on impatience, this means risk aversion and the propensity to consume will be correlated through their mutual dependence on impatience. For optimists, the correlation will be positive, whereas for the pessimists, it will be negative.

Consider an investor at time t with a remaining lifespan of $T-t$. Following Meyer, the utility of his remaining consumption stream will be taken to be the following:

$$(1)\quad U_t = \delta \exp\left\{\gamma \int_t^T \alpha^s u(c(s))ds\right\}$$
$$= \lim_{\Delta t\to 0} \delta \exp\left\{\gamma\alpha^t u(c(t))\Delta t\right\} U_{t+\Delta t}$$
$$\delta = \begin{cases} +1 & \gamma > 0 \\ -1 & \gamma < 0 \end{cases}$$

In (1), $u(c)$ is the utility of consuming at the rate c at any instant of time, α is a discount factor reflecting impatience which satisfies $0<\alpha<1$, and γ is a parameter which will turn out to be related to risk aversion in portfolio selection in the solution to be obtained below. It is to be noted that the additive family studied by Merton can be obtained from (1) by expanding in terms of γ, letting γ approach zero, and disregarding terms of order γ^2 or smaller.

The investor's net worth at t is denoted by w_t. There are two securities available for investment, one risky and the other riskless. Let z_{1t} be the proportion of net worth invested in the risky security, and let $1-z_{1t}$ be

* Professor of business administration, University of California, Berkeley.

the proportion invested in the riskless one. The risky return is taken to be infinitely divisible and normally distributed. Denoting the return over Δt by $r_t(\Delta t)$, the mean and variance of $r_t(\Delta t)$ are taken to be $\mu\Delta t$ and $\sigma^2\Delta t$ for any Δt. The return on the riskless security is taken to be $\rho\Delta t$. It is assumed that $\mu > \rho$. The proportionate rate at which net worth is consumed will be denoted z_{0t}. The consumption rate is therefore: $c(t) = z_{0t}w_t$.

Let $V(w_t, t)$ denote the maximum expected value of U_t, given w_t, and that an optimal policy is followed in t and subsequently. Use of (1) and application of the optimality principle gives the following relation which must be satisfied by V for small Δt:

$$(2) \quad V(w_t, t) = \underset{z_{0t}, z_{1t}}{\text{Max}} \exp\left\{\gamma\alpha^t u(z_{0t}w_t)\Delta t\right\} E\left\{V(w_{t+\Delta t}, t + \Delta t) \mid w_t\right\}$$

For small Δt, the dependence of investment income on consumption withdrawal over Δt can be neglected so that $w_{t+\Delta t}$ is given as follows:

$$(3) \quad w_{t+\Delta t} = (1 + \rho\Delta t + (r_t(\Delta t) - \rho\Delta t)z_{1t} - z_{0t}\Delta t)w_t$$

Expanding the exponential in (2) with respect to Δt; expanding $V(w_{t+\Delta t}, t+\Delta t)$ with respect to both its arguments about w_t and t, respectively; and making use of (3) and the properties of $E\{r_t(\Delta t)\}$ and $\text{Var}\{r_t(\Delta t)\}$; one obtains for small Δt (neglecting terms of order $(\Delta t)^2$ or less):

$$\begin{aligned}(4) \quad V(w_t, t) = \underset{z_{0t}, z_{1t}}{\text{Max}}\, & V(w_t, t) \\ & + (\rho + (\mu - \rho)z_{1t} \\ & - z_{0t})\Delta t w_t V_w(w_t, t) \\ & + \Delta t V_t(w_t, t) \\ & + 1/2\, \sigma^2 \Delta t z_{1t}^2 w_t^2 V_{ww}(w_t, t) \\ & + \gamma\alpha^t u(z_{t0}w_t)\Delta t V(w_t, t)\end{aligned}$$

where V_w, V_{ww}, and V_t have been used to denote partial derivatives with respect to the first and second arguments of V. Dropping $V(w_t, t)$ from both sides of (4), dividing by Δt, suppressing the t subscript on the state and decision variables, and suppressing the arguments of V and its partial derivatives gives:

$$\begin{aligned}(5) \quad 0 = \underset{z_0, z_1}{\text{Max}}\, & (\rho + (\mu - \rho)z_1 - z_0)wV_w + V_t \\ & + 1/2\, \sigma^2 z_1^2 w^2 V_{ww} + \gamma\alpha^t u(z_0 w)V\end{aligned}$$

The optimal policy must satisfy the partial differential equation given in (5). The equation in (5) agrees with that given by Meyer with the following exceptions: V_t is not taken to be equal to zero even when $T = \infty$, since V and the optimal policy depend on t; α is not suppressed by setting $\alpha = 1$ since having $0 < \alpha < 1$ is necessary for the proper covergence of V when $T = \infty$; and the sign of γ is not assumed to be negative, as having risk aversion either increasing or decreasing with age is taken to be a logical possibility.[1] The equation in (5) agrees with that given by Merton except that the last term containing $u(c)$ is multiplied by V, reflecting the fact that the multiplicative and not the additive family is being considered.

When $u(c) = \ln c$, an analytic solution can be obtained to (5) for either a finite or an infinite horizon. The latter can be obtained directly or as a limiting form of the finite case, providing $0 < \alpha < 1$ as is being assumed. For simplicity, only the solution to the infinite case will be derived here. Portfolio selection behavior in either case is of the same form. The solution is given in the following theorem:

THEOREM: *The solution to the lifetime portfolio selection problem in continuous time for* $u(c) = \ln c$ and $T = \infty$ *is as follows:*

$$\begin{aligned}(6) \quad V &= a(t)w^{\lambda(t)} \qquad \lambda(t) = -\gamma\alpha^t/\ln\alpha \\ a(t) &= \delta(-\ln\alpha)^{\lambda}\exp\left\{-\lambda(1 + \rho/\ln\alpha)\right\} \cdot (1 - \lambda)^{(\mu-\rho)^2/2\sigma^2 \ln\alpha}\end{aligned}$$

[1] It is to be noted that having $\alpha = 1$, $T = \infty$, and $\gamma < 0$, as does Meyer, will mean necessarily that $V = 0$. This follows because a policy of investing all net worth in the riskless asset and consuming the riskless income will make $\int_t^\infty u(c(s))ds$ unbounded with certainty and hence:

$$V = E\left\{\exp\left\{-\int_t^\infty u(c(s))ds\right\}\right\} = 0$$

Presumably, many other policies will also give $V = 0$, so the problem is not well formulated.

$$\overset{*}{z}_{0t} = \overset{*}{z}_0 = -\ln\alpha$$

$$\overset{*}{z}_{1t} = (\mu - \rho)/\sigma^2(1 - \lambda)$$

To see that (6) is the solution to (5) under the specified conditions, substitute $u(c) = \ln c$ and the V given in (6) into (5). Using $wV_w = \lambda V$, $w^2 V_{ww} = \lambda(\lambda - 1)V$, and $V_t = \dot{\lambda} V \ln w + \dot{a}V/a$ (where the dot notation indicates the time derivative) gives:

$$(7) \quad 0 = \underset{z_0, z_1}{\operatorname{Max}} V[(\rho + (\mu - \rho)z_1 - z_0)\lambda + \dot{\lambda}\ln w + \dot{a}/a + 1/2\,\lambda(\lambda - 1)\sigma^2 z_1^2 + \gamma\alpha^t \ln(z_0 w)]$$

Taking δV outside the maximization operator because it is positive and independent of z_0 and z_1, and observing that $\dot{\lambda}\ \ln w + \gamma\alpha^t \ln w = 0$, gives the following:

$$(8) \quad 0 = \underset{z_0, z_1}{\operatorname{Max}} \delta[\lambda(\rho + (\mu - \rho)z_1 - z_0) + \dot{a}/a + 1/2\,\lambda(\lambda - 1)\sigma^2 z_1^2 + \gamma\alpha^t \ln z_0]$$

$$0 = \dot{a}/a + \lambda\rho + \lambda \underset{z_0}{\operatorname{Max}} \{-z_0 - \ln\alpha \ln z_0\} + \lambda \underset{z_1}{\operatorname{Max}} \{(\mu - \rho)z_1 - 1/2\,(1 - \lambda)\sigma^2 z_1^2\}$$

Solution of these two simple maximization problems gives $z_0^* = -\ln\ \alpha$ and $z_{1t}^* = (\mu - \rho)/\sigma^2(1 - \lambda)$, as stated in (6). It is to be noted that the maximum with respect to z_1 has been taken as internal and independent of constraints on margin purchases or short sales. Substitution of these solutions into (8) shows that V is the required solution, if $\dot{a}/a$ satisfies the following differential equation:

$$(9) \quad 0 = \dot{a}/a + \lambda\rho + \gamma\alpha^t(\ln(-\ln\alpha) - 1) + \lambda(\mu - \rho)^2/2\sigma^2(1 - \lambda)$$

By using the $a(t)$ given in (6), it is easily verified that this $a(t)$ does provide a solution to (9).

For finite T, the portfolio solution will be of the same form as (6) except that $\lambda = -\gamma\alpha^t(1 - \alpha^{T-t})/\ln\ \alpha$. The optimal propensity to consume is no longer independent of t, being given by:

$$\overset{*}{z}_{0t} = -\ln\alpha/(1 - \alpha^{T-t})$$

The expression for $a(t)$ is considerably more cumbersome.

As shown in the introduction, the limiting case as $\gamma \to 0$ for (1) gives the additive family. Here, the special case of the additive family with a logarithmic utility function is obtained. The solution for this has been given by Merton. It corresponds to the solution in (6) for z_0^* and z_{1t}^* with $\gamma = 0$ (i.e., $\lambda = 0$).

The solution in (6) for z_{1t}^* is easily interpreted to verify the results stated in the introduction. Differentiating z_{1t}^* with respect to t gives:

$$(10) \quad \frac{d\overset{*}{z}_{1t}}{dt} = -\gamma\alpha^t(\mu - \rho)/\sigma^2(1 - \lambda)^2$$

Thus, the proportion of the portfolio invested in the risky security increases with age if $\gamma < 0$ and decreases with age if $\gamma > 0$. The additive case with $\gamma = 0$ forms the watershed. Referring back to (5), this is easily related to the Arrow-Pratt index of relative risk aversion in portfolio selection. The optimal portfolio at any time is that obtained by maximizing $E\{V\}$. This may be seen as follows. For gambles, small relative to wealth, $E\{V\}$ is equal to a linear function of mean and variance where the coefficient of variance is $wV_{ww}/2V_w$, or $-1/2$ times the index of relative risk aversion. Here the gamble will be small, relative to wealth for small Δt. From (5) the optimal portfolio is given by

$$wV_w \underset{z_1}{\operatorname{Max}} \left\{\rho + (\mu - \rho)z_1 + \frac{wV_{ww}}{2V_w}\sigma^2 z_1^2\right\}$$

where the term in brackets is the required linear function of mean and variance of return. From the V given in (6) the index of relative risk aversion in portfolio selection at any time is $1 - \lambda(t)$. It will be greater or less than that of the logarithm (which is one) as γ is negative or positive. Thus, risk aversion in portfolio selection as measured by

this index is seen to rise or fall with age as risk aversion is less or greater than that of the logarithm.

Differentiating z^*_{1t} with respect to α gives

$$(11) \quad \frac{dz^*_{1t}}{d\alpha} = \gamma\alpha^{t-1}(\mu - \rho)(1 - t\, ln\, \alpha) / \sigma^2(1-\lambda)^2(ln\, \alpha)^2$$

Thus the proportion invested in the risky security increases or decreases with increasing patience as risk aversion is less or greater than that of the logarithm. The propensity to consume (i.e., $z^*_0 = -ln\, \alpha$) decreases with increasing patience. Therefore, risk aversion in portfolio selection and the propensity to consume will be negatively or positively correlated, as risk aversion is less or greater than that of the logarithm.

Social Return to Public Information Services: Statistical Reporting of U.S. Farm Commodities: Comment

By LAWRENCE N. SMITH AND BRUCE A. SCHERR*

In a recent issue of this *Review*, Yujiro Hayami and Willis Peterson present a practical application of Alfred Marshall's social welfare concepts.[1] Their approach, in the tradition of public goods analysis, seeks to measure the social returns to improvements in information about *U.S.* farm commodities. Their strong theoretical argument is jeopardized by their empirical evidence leading to exaggerated and unrealistic conclusions. We have two basic criticisms of their analysis: 1) they use highly inelastic demand elasticities for grains which exclude export and animal feed uses; and 2) their conclusions are dominated by the marginal social returns for only two of the seventeen commodities studied. Their distribution of returns raises specific questions about sampling techniques for the two commodities which may be more important than the broader issue of social returns to public information services.

I. Erroneous Use of Some Elasticities

The price elasticities of demand used by Hayami and Peterson for the three food grains and three feed grains create exaggerated returns and highly sensitive benefit-cost ratios of meaningless dimensions for practical government decision making. Government decision making, using benefit-cost ratios, requires both a "yes we do" (or "no we don't") decision as well as a "how far do we go" decision. The Hayami and Peterson analysis appears to suggest that government should invest in sampling improvements to reduce typical sampling error for all commodities to the 0.0 percent level. For a 0.0 percent sampling error complete enumeration is required which we are sure was not the intent of the analysis.

The logic of the theoretical argument presented is that the more inelastic the demand function for a given commodity, the greater is the potential for increased social returns. The elasticities, taken from G. Brandow, p. 59, range from −.01 to −.04 for oats, barley, wheat, corn, rye, and rice. Brandow specifically states that these elasticities exclude the quantities demanded for export or for feed.

Using Hayami and Peterson's method, the 15.8 percent sampling error in reporting annual rice production could set off an inventory holding action which would last until the price of rice increased 395 percent to $24.75 per cwt. The inflated price according to their estimation, would cause a social loss of $289.6 million as the error is allowed to run its course. In all important applications of the concept of consumer surplus, Marshall concerned himself solely with the range of normal price variation.[2] Furthermore, historically (last 15 years) the greatest annual change in rice prices was $.59 (13 percent) and the average annual change in price was only 2.6 percent.

For the years included in the Hayami and Peterson study (1966–68) 9 percent of *U.S.* corn production was used for human food and industrial use and only 5 percent of the oats. Thirty percent of the barley produced was used for human food and industrial use.[3] This indicates that the demand elasticities used should be for combined uses, and that social loss, as defined by Hayami and Peterson, should be figured on a crop value for human food and industrial use for the six food grains.

Brandow, in the same reference used by Hayami and Peterson states, "... rough estimates place the elasticity for low-protein

TABLE 1—A COMPARISON OF ESTIMATES OF MARGINAL SOCIAL BENEFIT-COST RATIOS CORRESPONDING TO REDUCTION IN TYPICAL SAMPLING ERROR IN THE SURVEY FOR STATISTICAL REPORTING OF FARM COMMODITIES, UNITED STATES, FROM HAYAMI AND PETERSON TO SMITH AND SCHERR, 1966–68.

Change in Typical Sampling Error (percent)	Hayami-Peterson		Smith-Scherr	
	Area Sample	Multiple Frame Sampling	Area Sample	Multiple Frame Sampling
from 3.0–2.5	824.0	824.0	312.0	312.0
2.5–2.0	619.0	619.0	238.0	238.0
2.0–1.5	93.0	106.0	39.1	44.4
1.5–1.0	57.0	60.0	22.5	23.7
1.0–0.5	7.4	13.0	2.8	4.8
0.5–0.0	1.0	1.6	0.3	0.6

feeds at −.36." He further suggests that the demand for corn for all purposes apparently has an elasticity of about −.50, and that the elasticities for the other feed grains could considerably exceed unity because they comprise so small a share of the total low protein feed supply.[4] Earlier work by Henry Schultz suggested an elasticity coefficient for corn at the farm level of −.77, for oats −.54 and for barley −.17. Recent work at Purdue by Peter Emerson (p. 155) found a price elasticity of demand for wheat for all uses of −.25 and for rice −.20.

It is not the purpose of this comment to engage in an exchange of contrary estimates of price elasticity of demand. With adjustments in demand elasticities for combined use, we found a 67 percent reduction in the total benefits generated when the sampling error is improved from 3.0 percent to 2.5 percent. Table 1 shows the more reasonable benefit-cost ratios which emerge when the elasticities referenced above for combined use for the six grains are used.

The new lower levels of return still fall within the 500 percent range allowed for inaccurate coefficients by Hayami and Peterson. Can error in excess of 1000 percent for the six grains be considered "good enough for government work"? The lower levels of return representing new lower bounds than those reported by Hayami and Peterson still appear to support arguments for improved crop information. The higher elasticities have the added advantage of lending credence to the benefit-cost ratios indicating a cutoff point short of complete enumeration at the 0.5 percent typical sampling error level.

II. Dominance of Rice and Potatoes

The Hayami and Peterson justification for improving public information services is largely based on rice and potatoes. Table 2 shows results using our adjusted elasticities when rice and potatoes are removed from the analysis. Before adjustment, 56 percent of the marginal social benefits from improved information came from rice and potatoes. If the elasticity for rice is adjusted upward as we suggest, then potatoes alone provide 54 percent of the marginal social returns. At the time of the 1964 agricultural census, rice made up .6 percent and potatoes .4 percent of U.S. total crop acres. Perhaps the research question should have been, "Should the government invest to improve crop information about potatoes?"

In the public goods tradition we ask, "Can the social returns to potato eaters be used to justify, as their analysis shows, a complete enumeration of all commodities?" With such a strikingly skewed distribution of returns, it would appear more appropriate to ask potato eaters and the potato industry to pay for the cost of their information knowing that benefits to the consumers of the other commodities are small, making it possible for benefits to be divided.

A more practical approach for Hayami

TABLE 2—COMPARISON OF MARGINAL BENEFIT-COST RATIOS AS CALCULATED BY SMITH AND SCHERR, CORRESPONDING TO CHANGES IN TYPICAL SAMPLING ERRORS, UNITED STATES 1966–68

Change in Typical Sampling Error (percent)	Marginal Benefit-Cost Ratio			
	With Rice and Potatoes		Without Rice and Potatoes	
	Area Sample	Multiple Frame Sampling	Area Sample	Multiple Frame Sampling
from 3.0 to 2.5	312.0	312.0	87.2	87.2
2.5 to 2.0	238.0	238.0	68.1	68.1
2.0 to 1.5	39.1	44.4	9.5	10.8
1.5 to 1.0	22.5	23.7	5.8	6.1
1.0 to 0.5	2.8	4.8	0.7	1.2

TABLE 3—PROPORTIONED SURVEY COST AND MARGINAL BENEFIT-COST RATIOS FOR SIX GRAINS, 1966–68

	Six Grains[a] (million dollars)						
Area Sample	1.2	1.32	1.45	2.04	2.78	6.03	21.88
Multiple Frame Sample	1.2	1.32	1.45	1.97	2.68	4.58	15.60
Typical Sampling Error, Major Commodities	3.0	2.5	2.0	1.5	1.0	0.5	0.0

Change in Typical Sampling Error (percent)	Marginal Survey Cost: Area	Marginal Survey Cost: Multiple Frame	Grains Inventory Adjustment (million dollars)	Grain Returns Relative to Grain Costs, Marginal Benefit-Cost Ratios: Area	Grain Returns Relative to Grain Costs, Marginal Benefit-Cost Ratios: Multiple Frame
from 3.0 to 2.5	0.12	0.12	27.1	225.0	225.0
2.5 to 2.0	0.13	0.13	19.1	146.0	146.0
2.0 to 1.5	0.59	0.52	11.9	20.0	22.0
1.5 to 1.0	0.74	0.71	9.5	12.8	13.3
1.0 to 0.5	3.35	1.90	5.5	1.6	2.8
0.5 to 0.0	15.85	11.02	3.3	0.2	0.3

[a] $\frac{6\text{ (Survey Cost)}}{17} = \text{Proportioned Cost}$

and Peterson would have been to place potatoes in their production adjustment model with more reasonable marginal social returns as a result. This approach could be justified since potatoes can be grown somewhere in the United States each season of the year.

The Hayami-Peterson analysis does not show the relationship between survey costs for each commodity and returns for each commodity. It should be apparent that crops covering less than 1 percent of total crop area would cost less to survey than the major commodities. We have prepared a table (Table 3) which uses survey costs proportioned evenly among commodities to arrive at benefit-cost comparisons for the six grains. Our results show a definite investment cutoff point at the 0.5 percent typical sampling error level using a stratified or multiple frame sampling method.

III. Conclusions

In conclusion we support the theoretical argument used by Hayami and Peterson if it is limited to the normal range of commodity price changes. We support efforts to improve farm commodity production information on the basis of adjusted elasticities and more specific benefit-cost relationships. Our major regret is that the article presented a careless empirical analysis, leading to meaningless benefit-cost ratios which are useless, if not misleading, for public decision making. Presumably, to provide guidelines for such decision making is what Hayami and Peterson's efforts—if not efforts of all economists—are supposed to accomplish.

Social Return to Public Information Services: Statistical Reporting of U.S. Farm Commodities: Reply

By YUJIRO HAYAMI AND WILLIS PETERSON*

We agree with Lawrence Smith and Bruce Scherr that the demand elasticities should apply to the total market demand for the commodities in question rather than to one particular market. However the choice of demand elasticities is not quite as simple as they might lead us to believe. It is necessary to keep in mind that the time allowed for quantity to adjust to price changes in the inventory adjustment model is relatively short. The adjustment period implicit in this model takes place within the crop year. In the case of feed grains, the quantity adjustment has to come largely from changes in the rate of feeding rather than from changes in livestock numbers. Since changes in the feeding rate generally are profitable over only a very narrow range for most classes of livestock, we would expect the short-run demand elasticities to be substantially less than long-run elasticities which allow for adjustments in livestock and poultry numbers.

The demand elasticities presented by G. Brandow which our critics would have us use are long-run elasticities that were applied to a long-run supply control model. As Brandow specifically states, "Adjustments thus described for the feed-livestock economy are long term and would take place with varying lags, probably coming most slowly in dairying" (p. 7). In regard to the elasticities, he points out, "The elasticities used in the model are intended to apply when enough time is allowed for livestock adjustments to take place and for *inventory changes to be unimportant*" (p. 9, italics added for emphasis). Although the authors do not specify whether they use Brandow's estimates or not, it is fairly clear that they use comparable figures in their calculations. Thus they apply long-run demand elasticites to a short-run adjustment model, which to us does not seem entirely appropriate either.

Although we welcome efforts to estimate demand and supply elasticities specifically applicable to the models at hand, we do not feel that much can be gained by searching the literature for parameters that may bias the estimates one way or another. The results are not likely to change the overall conclusions of the study. Indeed the estimates presented by Smith and Scherr fall within the range of estimates presented in Table 5 of our article. This table is not intended to bracket the true values, as our critics imply, but mainly to illustrate that the marginal benefit-cost (B/C) ratios of increasing the overall average sampling accuracy from 2.0 to 1.5 percent remains relatively attractive even when we impose these rather severe downward biases on the data. The Smith-Scherr estimates show the same thing. Certainly we do not suggest that the sampling error be reduced to zero. When dealing with such gross figures as this, a B/C ratio in the neighborhood of one certainly would not be considered attractive. However, it should be stressed that the estimates presented in Table 4 of the original article already contain a downward bias in that the inventory adjustment model is applied only to crops and the production adjustment model is applied only to livestock.[1]

In reference to the dominance of rice and potatoes in the social returns, we should point out that the article deals only with a specific and fairly narrow range of sampling errors. Within a different range, such as between 5 and 10 percent, we might reasonably expect other commodities such as wheat and corn to provide the major share of the

* Professors, Tokyo Metropolitan University, and University of Minnesota, respectively.

[1] We should also point out that an additional social return is likely to be forthcoming if the government can use such information to obtain a more efficient allocation of its investment expenditures.

returns. Of course, if data were available on the relationshlp between sampling cost and error of specific commodities the B/C ratios could be estimated for each commodity separately. We did not do this because the data were not available to us.

In regard to the wide range of price changes implied by the sampling errors and demand elasticities, it is necessary to bear in mind that the sampling errors are averages of errors inherent in a number of surveys conducted from planting to harvest. Naturally the expected price would come closer to the market clearing price as harvest time approaches. As an analogy, it is considerably easier to predict the score of a football game in the fourth quarter than before the game begins. Given sufficient information, it would be possible to calculate the social returns of additional information that is made available during the crop year.

We would hope that this comment and reply does not detract from what is perhaps the most important aspect of the article, namely that investment in market information can be viewed as yielding a social return to society in general as opposed to only a means of increasing short run profits to primary producers or marketing firms.

On Ignorance and Equal Distribution

By AMARTYA SEN*

There has recently been a revival of interest in Abba Lerner's proposition on maximization of probable aggregate welfare through a policy of equal distribution in a situation of Bayesian ignorance as to who has which utility function. Maurice McManus, Gary Walton, and Richard Coffman, and Roger McCain have presented in the June 1972 issue of this *Review* formal versions of Lerner's theorem based on explicit formulation of probability distributions of utility functions for different individuals. Further, McManus et al. have shown that the optimality of equal distribution holds also under the "maximin" strategy of maximizing the lowest value of aggregate welfare for any distribution, and this result does not, naturally, depend on the exact assumptions about probability distributions. As it happens, these two theorems were stated and proved in my paper presented to the International Economic Association Round-Table Conference on Public Economics in Biarritz in 1966 and were published in Sen (1969) as Theorems II ("Probabilistic Egalitarianism") and III ("Maximin Egalitarianism").

This fact in itself is scarcely interesting, except conceivably to the authors and editors, but what may interest the readers of this journal is the fact that both these theorems can be substantially generalized by dropping the framework of *additive* social welfare functions and only requiring social welfare to be a concave (or quasi-concave) function of individual utilities, which need not even be separable.

This generalization is of particular relevance in the context of Milton Friedman's penetrating criticism of Lerner's approach:

> Eliminate the assumption of ignorance, and the same analysis immediately yields a justification of inequality if individuals do differ in capacity to enjoy satisfaction. . . . Suppose, further, that it is discovered by this technique that a hundred persons in the United States are enormously more efficient pleasure machines than any others, so that each of these would have to be given an income ten thousand times as large as the income of the next most efficient pleasure machine in order to maximize aggregate utility. Would Lerner be willing to accept the resulting division of income as optimum . . . ? [pp. 310–11]

The theorems presented below indicate that Lerner does not have to do any such thing since the maximizing property of the equal distribution holds for probable social welfare even if it is not of the additive form. A concave social welfare function W need not necessarily award a higher income to a more efficient pleasure machine.[1] The "maximin" result presented in Sen (1969) and McManus et al. can also be similarly generalized.

I

The results are proved for the case in which there are n individuals and n utility functions, when it is not known who has which utility function.[2] The following notation is used:

y = any income vector $(y_1, \ldots, y_n)$, in which y_i is the income of person i

z = vector of equal incomes, i.e., $z_i = z_j$ for all i, j

U^j = individual welfare function j

W = social welfare

u_i = individual welfare of person i

p_i^j = probability of person i having U^j

* Professor of economics, London School of Economics.

[1] This is an important issue for the measurement of income distribution, on which see Partha Dasgupta, Sen, and David Starrett, and Michael Rothschild and Joseph Stiglitz. I have discussed the underlying normative framework in my forthcoming book. The "Weak Equity Axiom" used there would guarantee that the more efficient pleasure machine would get, in fact, *less* income, and this is consistent with a concave social welfare function. See also Sen (1970), ch. 9.

[2] We can take a wider set V of individual welfare functions and extend the proofs. On this see Sen (1969).

ASSUMPTION 1 (*Total Income Fixity*): The total income to be distributed is constant (y^*):

$$(1) \qquad y_1 + \ldots + y_n = y^*$$

ASSUMPTION 2 (*Concavity of the Group Welfare Function*): Social Welfare W, an increasing and symmetric function of individual welfare levels: $W = W(u_1, \ldots, u_n)$, is concave.

ASSUMPTION 3 (*Concavity of Individual Welfare Functions*): Each individual welfare function $U_j(y)$ is concave.

ASSUMPTION 4 (*Equi-probability*): For each j, $p_i^j = p_m^i$, for every pair of individuals i, m.

THEOREM 1: *Given Assumptions 1, 2, 3 and 4, the mathematical expectation of social welfare is maximized by an equal division of income.*

PROOF:

Thanks to the symmetry property of W, we can take the social welfare function to be $W(u^1, \ldots, u^n)$, where u^j is the utility of the person with the jth utility function; nothing depends on precisely which numbered individual enjoys U^j. Corresponding to any income distribution vector y, let $\bar{y}$ be a permutation of it such that $\bar{y}^j$ is the income going to the person with the jth utility function. There are $n!$ different ways of assigning n individual welfare functions to n persons, and corresponding to each such assignment k, we have a permuted vector $\bar{y}(k)$, for any income vector y. Therefore for any distribution y, there are $n!$ values of social welfare given by $F(\bar{y}(k))$, for $k = 1, \ldots, n!$, and given Assumption 4, the expected value of social welfare from y is given by:

$$(2) \qquad E(y) = \frac{1}{n!} \sum_k F(\bar{y}(k))$$

Of course, since all permutations z of the equi-distribution vector z are the same:

$$(3) \qquad E(z) = F(z)$$

By Assumptions 2 and 3, F is a concave function, and by Assumption 1, we have:

$$(4) \qquad z = \frac{1}{n!} \sum_k \bar{y}(k)$$

Since F is concave, it is clear that:

$$(5) \qquad E(y) \leq E(z)$$

Since this is true of all y, Theorem 1 holds.

II

For the "maximin" result, Assumption 4 is weakened to:

ASSUMPTION 4* (*Shared Set of Welfare Functions*): For any individual i and any welfare function j, it is possible that i has j. Nothing is said on relative probabilities.

For the existence of minimal individual welfare levels, something has to be assumed about the lower bounds of these functions. The following simple assumption is sufficient.[3]

ASSUMPTION 5 (*Bounded Individual Welfare Functions*): Each individual welfare function U^j is bounded from below.

THEOREM 2: *Given Assumptions 1, 2, 3, 4*, and 5, the maximin strategy for social welfare is to distribute income equally.*

PROOF:

Since z is an average of $\bar{y}(k)$ for all k, for any quasi-concave welfare function F, we must have:

$$(6) \qquad F(z) \geq \operatorname*{Min}_k F(\bar{y}(k))$$

Furthermore, z being an equal division, the value of $\bar{z}$ is invariant with respect to interpersonal permutations of individual welfare functions. Hence Theorem 2.[4]

Friedman's criticism of Lerner, quoted above, treats him as a prisoner of utilitarianism, but Lerner is free to leave the Benthamite jail.

[3] It can, however, be easily weakened.

[4] Note that for this result even Assumption 2 is much too strong and the quasi concavity of W is sufficient.

Specification Error In Macro-Econometric Models: The Influence of Policy Goals

By JAMES R. CROTTY*

Econometric estimation of macro-economic relations has typically been based on the assumption that the monetary and fiscal instruments of the government are exogenous variables whose movements are not predicated in any systematic way on changes in economic conditions. Yet it has been recognized for some time that this assumption is in fact incorrect, and that any estimation procedure which relies on this assumption may be subject to important specification error. John Wood, for example, has cautioned that "If government policy makers do not behave randomly with respect to economic events . . . " then the typical estimation procedure " . . . results in inconsistent estimates of the parameters in equations describing the behavior of the private sector of the economy" (p. 135). Michael Hamburger, pursuing Wood's lead, has argued for a new approach which recognizes " . . . that it is the ultimate objectives of . . . policy (e.g., the desired rate of inflation) that should be treated as exogenous rather than the instruments used to achieve the objectives" (p. 34).

The purposeful nature of economic policy has not only been recognized by most economists; in the work of Henri Theil and the Netherlands School we have been provided with a formal theory of optimal government economic policy.[1] It assumes that the government or state behaves as if it possesses a preference function which orders possible outcomes related to a set of economic instrument and goal variables. The goals are related to the instruments through a representation of the structure of the economy. The purpose of this paper is to use the Theil framework to demonstrate explicitly the serious nature of the specification error that may arise if the preference function underlying government policy is ignored in macroeconometric work. The analysis is developed in a reduced-form context, but the specification error discussed in the paper applies to structural estimation as well.

I. The Model

Following Theil, we make the following two assumptions:

1) All vectors $X=[X_h]$, $Y=[Y_i]$ of instruments and noncontrolled or goal variables, respectively, are real valued. Deviations $\overline{X}=[X_h-X_h^*]$ and $\overline{Y}=[Y_i-Y_i^*]$ of these variables from their desired values, X^* and Y^*, are ordered according to the state decision maker's preference such as to allow a representation by means of a quadratic disutility function:[2]

$$W(\overline{X},\overline{Y}) = \alpha'\overline{X} + \beta'\overline{Y} + 1/2\,(\overline{X}'A\overline{X} + \overline{Y}'B\overline{Y} + \overline{X}'C\overline{Y} + \overline{Y}'C\overline{X})$$

where $\alpha=[\alpha_h]$, $\beta=[\beta_i]$, $A=[a_{hk}]$, $B=[b_{ij}]$, $C=[C_{hi}]$ are vectors and matrices of fixed elements and appropriate order. For ease of exposition we will treat the C matrix as null, implying that the state does not associate specific tools with specific goals, and assume that A is diagonal, implying that the state is not concerned with the relative position of the instruments.

2) The vectors X, Y are connected by a

* Assistant professor of economics, Bucknell University. I am grateful to Michael Hamburger, Leonard Rapping, the managing editor, and especially Raford Boddy for helpful suggestions. The reader's attention is directed to a recent article by Stephen Goldfeld and Alan Blinder which deals with problems similar to those discussed in this paper but which appeared too late to be incorporated here.

[1] See Theil for an extensive discussion of the theory and applications of his approach.

[2] The term X^* refers to preferred levels of instruments abstracting from their impact on Y. For an explanation of the necessity of including the instruments in the state preference function, see Theil, p. 80, and Arthur Okun, pp. 128–34.

linear equation system $Y=RX+S$ where $R=[r_{ih}]$ is a matrix of fixed elements describing the multiplicative structure of the constraints related to instruments and $S=[s_i]$ is a vector of fixed elements describing the additive structure. The system $Y=RX+S$ is the reduced form of the economy, which is a constraint in the state's decision problem. We abstract from any uncertainty associated with the reduced form and treat the problem as one of certainty equivalence.

The model thus characterizes an optimal decision-making problem in which the state wishes to handle its policy instruments in such a way as to minimize the value of its quadratic disutility function subject to the constraints represented by the reduced form of the economy. In other words, the problem is to choose X in order to:

$$\text{(1)} \qquad \text{minimize } W=\alpha'\overline{X}+\beta'\overline{Y}+1/2\,[\overline{X}'A\overline{X}+\overline{Y}'B\overline{Y}]$$
$$\text{subject to } Y=RX+S$$

We can find the optimal value of the instruments, X^0, by substituting the constraint into the preference function, partially differentiating with respect to the vector X, and setting the resulting expression equal to the zero vector.

$$\text{(2)} \qquad \frac{\partial W}{\partial X}=(\alpha+R'\beta)+A\overline{X}+R'B\overline{Y}=0$$

or

$$\text{(3)} \quad \alpha+A(X-X^*)=-R'\beta-R'B(Y-Y^*)$$

These expressions represent the first-order conditions for an optimal choice, i.e., they must hold at $X=X^0$. They are not the linear decision rules generally associated with quadratic preference function problems. Linear decision rules or response functions relate X^0 to exogenous and lagged endogenous variables. In this case, the linear decision rules would be

$$X^0 = X^0(S,\ Y^*,\ X^*;\ \alpha,\ \beta,\ A,\ B,\ R)$$

The expressions in (3) are the marginal utility conditions characterizing an optimal policy. The left-hand side of the equations are estimates of the marginal changes in utility resulting from movements in X. The right-hand side are the marginal changes in utility which would come about through the resultant movements in Y. At X^0 they must balance

Since most macro-economic reduced-form regressions have Y as the dependent variable, we must rearrange the optimality conditions. For convenience, assume that R is a square matrix. That is, we assume that there are an equal number of goals and instruments. Note that this does not imply that all desired values can be achieved simultaneously.[3]

$$\text{(4)} \quad \overline{Y} = -(R'B)^{-1}(\alpha+R'\beta)-(R'B)^{-1}A\overline{X}$$

Because reduced-form regressions are generally not in deviation form, transform (4) as follows:

$$\text{(5)} \quad Y = -(R'B)^{-1}(\alpha+R'\beta)+Y^* + (R'B)^{-1}AX^*-(R'B)^{-1}AX$$

If we assume that Y^* and X^* do not change over time, i.e., that the policy problem is exclusively one of stabilization, we can write (5) as:

$$\text{(6)} \qquad Y=\delta-(R'B)^{-1}AX$$

where δ is a vector of constants.

The optimality condition, (6), is a relation between Y and X. It is *not* the reduced form. The reduced form, $Y=RX+S$, is a constraint on the state in this model. Both sets of relations, $Y=\delta-(R'B)^{-1}AX$ and $Y=RX+S$, must be satisfied. It will be shown below that, with respect to the role of R, the relation between Y and X in the optimality

[3] If the state is able to achieve all of its desired values for goals and instruments simultaneously, then the preference function parameters have no empirical significance and the reduced-form parameter estimates are free of the particular specification error which is the concern of this paper. For a discussion of this case, see Wood, pp. 157–60. However, the argument that, with respect to major economic goals and policy instruments, the economy has always been approximately where the state desired it to be might be rather embarrassing to the state policy makers.

condition may be different than—indeed even the opposite of—their relation in the constraint. Coefficients of a regression relating Y to X will generally be influenced by both (6) and the reduced form constraint. This situation is similar to the price-quantity relation in the demand and supply functions for a commodity. Price-quantity time-series data will tend to trace out whichever function is relatively more stable over the sample period. Under the assumptions of this model, the reduced form is a relation between Y and X, *given* S. The optimality condition is a relation between Y and X, *given* Y^* *and* X^*. Regression estimates will be dominated by whichever relation is relatively more stable over time: S clearly changes every period, shifting the reduced form $Y-X$ relation; Y^* and X^* may change, in which case the optimality condition $Y-X$ relation will shift. If the former shift is larger than the latter the optimality condition will dominate the regression estimates.

We will examine two static cases, i.e., cases in which the state in its planning is concerned only with the current period. Assume for both cases that the state has two goals, Y_1 and Y_2, and two instruments, X_1 and X_2. We are concerned with the interpretation of the estimated coefficients from a linear regression relating Y_1 as the independent variable to X_1 and X_2. The question at issue is: What can we validly infer from the relative size of the regression coefficients about the impact multipliers, r_{11} and r_{12}, of the reduced form? Since we are concerned in this paper with the direction and extent of the specification bias caused by neglecting to consider the goals of the state, we will assume that the regression coefficients are estimates of the optimality conditions. This assumption will enable us to judge the extent of the maximum specification bias. The maximum bias would occur, as suggested above, when the reduced-form $Y-X$ relation exhibited large shifts over time relative to the optimality condition $Y-X$ relation.

Case 1

Assume that B is a diagonal matrix. This implies that the cardinal disutility measure associated with a squared deviation of Y_1 from Y_1^* does not depend on the level of $\overline{Y}_2$, and conversely. With this specification, the $\overline{Y}_1$ regression would yield estimates of the following relation:

$$(7)\qquad Y_1 = \delta_1 - \frac{a_{11}b_{22}r_{22}}{b_{11}b_{22}(r_{11}r_{22} - r_{21}r_{12})} X_1 + \frac{a_{22}b_{22}r_{21}}{b_{11}b_{22}(r_{11}r_{22} - r_{21}r_{12})} X_2$$

Given the knowledge that the regression coefficient of X_1 is larger in absolute value than that of X_2, what can we validly infer about the relative absolute values of r_{11} and r_{12}? In this case, the answer is almost nothing! A large relative regression coefficient for X_1 would imply either:

1) a_{11} is larger than a_{22}. This means that the state is more concerned about moving X_1 away from its desired value than it is about moving X_2.

And/or

2) r_{22} is larger than r_{21}. This implies that the impact on Y_2 of X_2 is more powerful than that of X_1.

Case 2

Assume that B is not a diagonal matrix so that the utility associated with one goal depends upon the condition of the other goal. This yields the following relation:

$$(8)\qquad Y_1 = \delta_1 - \frac{a_{11}(r_{12}b_{12} + r_{22}b_{22})}{N} X_1 + \frac{a_{22}(r_{11}b_{12} + r_{21}b_{22})}{N} X_2$$

where $N = (b_{11}b_{22} - b_{21}b_{12})(r_{11}r_{22} - r_{21}r_{12})$

As with Case 1, we cannot infer from larger regression coefficients for X_1 than X_2 anything about the relative size of r_{11} and r_{12} unless we know the relative sizes of the other parameters. This case does introduce a particularly perverse condition however. Note that r_{12} appears in the numerator of the X_1 coefficient while r_{11} appears in the numerator of the X_2 coefficient. Therefore, under many plausible assumptions about the size of the

parameters other than r_{11} and r_{12} we would find that a relatively large regression coefficient for X_1 as opposed to X_2 would indicate that X_2 was really more powerful than X_1.

II. The Role of Lagged Instruments

Reduced-form regressions frequently include lagged instrument values as independent variables. There are several ways to generalize the preference function framework in order to show that current values of the goals may be related to both current and lagged values of the instruments in such a way that the regression coefficients of lagged instruments contain both reduced-form and preference function parameters. For example, consider a static state preference function in which the disutility associated with current $\overline{Y}_t$'s depends upon their lagged values. Such a function would represent a situation in which the state's concern with an unemployment rate which was 1/2 percent above the desired value would be different if the unemployment rate was rising than if it was falling. One example of this class of preference functions would be:

$$(9)\quad W(\overline{X}_t, \overline{Y}_t) = \alpha'\overline{X}_t + \beta'\overline{Y}_t + 1/2\,[\overline{X}_t' A\overline{X}_t + \overline{Y}_t' B\overline{Y}_t + \overline{Y}_t' D\overline{Y}_{t-1}]$$

where the subscripts refer to time periods.

The optimal choice conditions for this function are:

$$(10)\quad \frac{\partial W}{\partial X_t} = (\alpha + R'\beta) + A\overline{X}_t + R'B\overline{Y}_t + R'D\overline{Y}_{t-1} = 0$$

or, under the assumption that R is a square matrix:

$$(11)\quad \overline{Y}_t = -(R'B)^{-1}(\alpha + R'\beta) - (R'B)^{-1}A\overline{X}_t - (R'B)^{-1}D\overline{Y}_{t-1}$$

Since $Y_{t-1} = RX_{t-1} + S_{t-1}$ we have:

$$(12)\quad \overline{Y}_t = -(R'B)^{-1}(\alpha + R'\beta) - (R'B)^{-1}A\overline{X}_t - (R'B)^{-1}D(RX_{t-1} + S_{t-1} - Y^*_{t-1})$$

In general, S_{t-1} will contain distributed lagged values of X. Therefore, (12) will relate $\overline{Y}_t$ to current and lagged values of X. Further the coefficients of both current and lagged values of the instruments will contain both preference function and reduced-form parameters.

III. Some Examples

Although the main purpose of the paper is to focus on the problem of specification error by presenting a general analytical framework, a few examples may help to make the basic implications more evident. The examples which follow are not presented as definitive explanations of actual empirical results. Rather they are designed to emphasize the importance of preference function considerations in the interpretation of macro-econometric analysis.

A specific example of macro-economic reduced-form estimation that largely mirrors the assumptions made above is the evidence presented by Leonall Andersen and Jerry Jordan in support of the St. Louis equation.[4] Andersen and Jordan assess the strength and reliability of monetary and fiscal policy through the use of regressions relating changes in nominal GNP to current and lagged values of frequently used indicators of monetary and fiscal action. They assume that this equation is a reduced form which is " . . . a derivable consequence of a system of equations which may be hypothesized to represent the structure of the economy (i.e., a so-called structural model)" (p. 16). On the basis of this assumption and their regression results they conclude that "The response of economic activity to monetary actions compared with that of fiscal actions is (I′) larger, (II′) more predictable and (III′) faster. . . . All of these implications point to the advisability of greater reliance being placed on monetary actions rather than on fiscal actions" (p. 22).

If we assume that the state is concerned with one other goal in addition to GNP, price stability for example, then the Andersen-

[4] For other tests of the St. Louis equation see Edward Corrigan, Richard Davis, Frank de Leeuw and John Kalchbrenner, Arthur Laffer and R. David Ranson, and William Silber.

Jordan regression equation is identical in form to equation (12). If we neglect lagged terms it is identical in form to equations (7) and (8). Under the assumptions of *Case 1*, the regression coefficients of the monetary and fiscal instruments tell us nothing about the relative size of their *GNP* multipliers, i.e., about the relative strength of monetary and fiscal policy. Under the assumptions of *Case 2*, a relatively large coefficient for the monetary as opposed to the fiscal instrument could, as explained above, indicate that the fiscal instrument was more powerful than the monetary instrument—a conclusion diametrically opposed to the one drawn by Andersen and Jordan from the same empirical evidence.

With respect to policy oriented reduced-form regressions in general, different assumptions about the role of instruments and goals in the state's preference function will lead to different expectations regarding the sign and relative size of regression coefficients. Suppose that the state believed that the existence of a Phillips' curve relationship made it unnecessary to use more than one instrument to simultaneously influence aggregate demand and the price level and attached no cost or disutility to movements of that instrument away from its desired value. The optimal use of the instrument for stabilization purposes would lead to the failure of standard reduced-form regressions to establish any relation between the instrument and the goals. Instrument movements would exactly counterbalance other forces tending to move the goal variables away from their desired values.[5] Therefore, if a fiscal variable was the sole or chief stabilizing instrument, we would expect it to have a regression coefficient not significantly different from zero. Under the assumption of quadratic instrument adjustment costs both instruments would be used. We would expect to observe correlations between goals and instruments which were opposite in sign to the respective reduced-form multipliers since the disutility attached to instrument adjustment would prevent complete goal variable stabilization.[6]

As a final example, assume that *GNP* and the interest rate are the two goal variables. The interest rate might be included either because it was considered to be a goal variable in and of itself or, more likely, because it served as an intermediate operating policy target variable. Any change in demand or expenditure variables which tended to push *GNP* above its desired level would also tend to raise the level of the interest rate above its desired value. If, in the face of such demand pressure, the state reacted by increasing the money supply or monetary base in an attempt to keep the interest rate stable we would observe a positive correlation between *GNP* and the monetary instrument.[7] This possibility is most likely to occur if the monetary authority is associated in a special way with the interest rate target. Since central banks do seem to place important emphasis on financial market and interest rate stability, this line of reasoning may offer a partial explanation of the fact that reduced-form regressions of the St. Louis variety consistently establish positive coefficients for the money supply or monetary base.

IV. Conclusion

The fundamental conclusion of this paper is that if the government is using its policy instruments in a systematic attempt to influence economic activity, there may be substantial specification error in any macroeconomic empirical work which does not utilize policy response functions. The policy decision-making process can generate relation-

[5] John Kareken and Robert Solow, p. 16, have pointed out this pitfall in the interpretation of regressions relating policy goals and instruments.

[6] See Brainard for a case in which incomplete goal variable stabilization results from the uncertainty attached to the policy maker's estimates of the reduced-form multipliers.

[7] This explanation of a positive money supply regression coefficient was suggested by Hamburger. Okun, p. 151, discusses the possibility that Federal Reserve policy may produce a positive relationship between the money supply and *GNP* by accommodating changes in the demand for money which arise from shifts in aggregate demand for goods and services. A related explanation by Kochin is that the monetary authorities consistently overreact to changes in aggregate demand by adjusting the money supply by more than is necessary to achieve stabilization.

ships between variables which are unrelated to or even inversely related to the true parameters of the economic structure or model. The specification error is potentially quite severe. Therefore, the parameters of the economic model will have to be estimated jointly with those of the state preference function.

Import Controls on Foreign Oil: Comment

By Ryan C. Amacher, Robert D. Tollison, and Thomas D. Willett*

The question of whether controls on the importation of foreign oil into the United States should take the form of tariffs or quotas has been a topic of recent public debate and investigation by economists. Under static competitive conditions it is well known that equivalent tariffs and quotas can be constructed. Hence in this context, there is no choice to be made on economic efficiency grounds.[1] However, in a recent issue of this *Review*, George Hay points out that the actual market for oil in the United States differs from the required textbook conditions for equivalence. Under the *U.S.* oil import program which prevailed until recently, each refiner's quota for import of foreign oil is a positive function of his refinery input. Since import tickets are allocated free of charge, rather than auctioned, the form of the quota lowers the marginal cost of domestic refiners. Hay goes on to show that when combined with other static competitive assumptions, this quota mechanism could generate greater consumer benefits in terms of lower prices than would an equivalent tariff (equivalent in the sense that the same percentage of imports is admitted).[2]

Hay expresses a preference for tariffs in a real world context and warns that his analysis of the price effects of the *U.S.* oil quota system holds only under very restrictive conditions. However, he does not address what is perhaps an even more important deviation of the domestic oil industry from the standard textbook model: crude oil production in the United States was limited in the major producing states by regulatory commissions that practiced market demand prorationing under the old oil quota program. Under this system, any price set by the industry is ratified by the commissions by limiting production to a level that will not result in the accumulation of undesired inventories.[3]

We are not addressing the issue of the level of price in the oil industry in this paper. Rather, we wish to review the effects of tariffs and quotas on resource allocation, an issue which Hay omits from his analysis; and, for this purpose we make use of the simple model of a profit-maximizing monopoly as a characterization of the domestic oil industry. The assumption of profit maximiza-

* University of Oklahoma; U.S. Council of Economic Advisers and Texas A&M University; and U.S. Treasury; respectively. Tollison and Willett were at Cornell University during the original drafting of the paper. Without necessarily implying agreement with all parts of our analysis, we should like to thank George Borts, George Hay, Edward Mitchell, Edward Tower, and an unknown referee for helpful comments on an earlier draft and the Bureau for Business and Economic Research, University of Oklahoma, for drafting services.

[1] See Jagdish Bhagwati (1955, 1968), Hirofumi Shibata, and Tsvi Ophir. As has been noted by a number of economists, on economic efficiency grounds neither a tariff nor a quota is probably the first best method of correcting for the national defense externalities associated with the oil market.

[2] Hay assumes the domestic supply of crude oil can be taken to be essentially unlimited at a constant price. Assuming that the prices of both foreign and domestic crude oil are fixed, it is easy to show that a quota system that allocates import tickets as a subsidy to refinery inputs results in lower consumer prices of refined products than a tariff which collects the foreign-domestic price differential for the Federal Treasury. This conclusion, as Hay points out, does not arise from any geographic considerations. If all domestic production and refining were at one point, it would still hold. Except in unusual circumstances all crude oil imported to Petroleum Administration for Defense (*PAD*) districts I–IV is used by refineries on the East Coast, the end point in Hay's analysis.

[3] This process of industry pricing is consistent with a number of models of price level formation in the industry. For example, it is consistent with a model stressing that colluding firms (in this case, the prorationing authorities) may limit price in order to forestall government entry through import or antitrust action. Hay notes the existence of prorationing, but uses it as an explanation for his assumption that the offer curve of domestic producers (at the wellhead) is horizontal for broad segments (1971, p. 688). He appears to have in mind a description of the industry that views the regulatory agency as attempting to maintain constant prices for given periods of time. For further discussion of the structure of the oil industry, see the Cabinet Task Force on Oil Import Controls, especially pp. 81 and 121.

tion is sufficient to show the differential effects of a tariff and quota on resource allocation in the industry. In this formulation the level of domestic reserves, and hence production, depends upon the price when the domestic industry is viewed as a profit-maximizing monopoly setting prices. As is well known under conditions of potential or actual domestic monopoly, the equivalence between quotas and tariffs breaks down.[4] The relevance of this point to the oil import question was stressed by the report of the Cabinet Task Force on Oil Import Control. As is illustrated below, where the foreign elasticity of supply to the domestic market is high (as it is in the case of oil), a nonprohibitive tariff still allows imports to overcome the misallocational effects of the domestic monopoly, while under a quota this would not be the case.

I. A Graphical Analysis

Figure 1 represents the market derived demand curve in the United States for crude oil. The colluding firms in this case behave like a textbook monopolist, setting marginal revenue (MR_m) equal to marginal cost (MC_m) with a resulting price of P_1 and output per unit of time of A. It can be shown

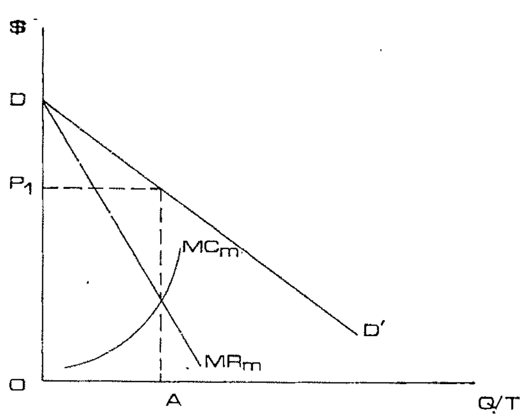

FIGURE 1: THE MONOPOLY WITH IMPORTS PROHIBITED

[4] See Bhagwati (1965) and Charles Kindleberger, pp. 566–68. We are concerned here with static comparisons. For another major condition for nonequivalence, caused by moving from a static to a dynamic model, see Mordechai Kreinin and Ingo Walter.

that P_1 will exceed the world price. Moreover, the domestic monopoly with imports prohibited results in the expected allocative inefficiency due to monopoly where marginal cost is less than price.

If the government introduced foreign sources of supply through a quota system, the market demand curve facing the domestic monopolist would shift to the left, as in Figure 2, by the amount of the quota ($C'D'$). The colluding firms would thus further restrict their output, maximizing short-run profit at price OP_2 and output OB.[5] The effect of the quota (as measured, for example, by the divergence of price and marginal cost in Figures 1 and 2) reduces but does not eliminate the market power of the domestic monopoly since marginal cost is still less than price.

If, instead of introducing the foreign supply of oil through quotas, the government had chosen an equivalent tariff (equivalent in that it established the same discrepancy between foreign and domestic price), the market power of the dominant domestic firms would have been severely constrained.[6]

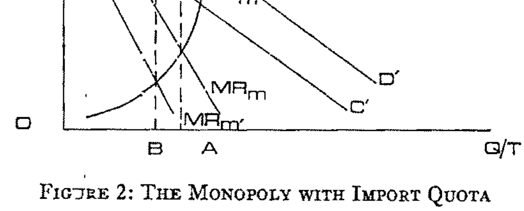

FIGURE 2: THE MONOPOLY WITH IMPORT QUOTA

[5] With a straight line demand curve (as drawn in Figure 2) there is an unambiguous shift in the monopolist's marginal revenue, indicating a decline in production. Under other assumptions (e.g., if the demand curve representing the domestic market is convex from below) it is uncertain whether the marginal revenue (and hence production) shifts up or down in response to an increase in the quota.

[6] Bhagwati demonstrated that in the presence of domestic monopoly a quota produces a higher price

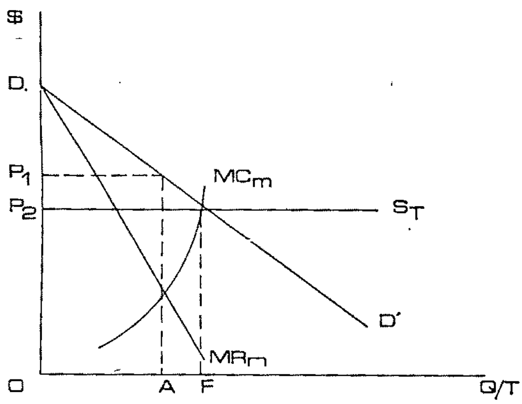

FIGURE 3: THE MONOPOLY WITH IMPORT TARIFF

In Figure 3 a tariff that establishes price OP_2 is levied. P_2S_T now represents the supply curve to the *U.S.* market. The once dominant coalition of firms, now without market power, produces output OF where price (OP_2) equals marginal cost. Market power is absent under the import tariff in the sense that in equilibrium the domestic price (the world price plus tariff) for crude no longer exceeds marginal cost.

The tariff and quota thus have quite different effects on the structure of the domestic oil industry. A quota allowed the domestic monopoly to maintain its power, since prorationing and excess capacity can continue to exist. The tariff, on the other hand, allows competitive supply at the world (plus tariff) price.[7] Under the tariff the domestic firms are forced to produce OF to the right of OA, while with the quota they are allowed to restrict output, producing OB to the left of OA.[8]

Switching to a tariff served to generate a better allocative solution by curbing domestic monopoly power and by stimulating an increase in domestic production. We suspect this allocative gain would considerably outweigh the type of potential price gains for consumers from a quota system as analyzed by Hay.[9]

(implicit tariff) than does a tariff that allows the same volume of imports (1965, p. 53). Since we are concerned with resource allocation comparisons and not price comparisons (an issue on which Hay's analysis is vulnerable in the case of domestic monopoly, see E. Mitchell et al.), we consider here a tariff that allows the correct volume of imports to establish an equivalent domestic price. This is consistent with the standard definition of equivalence.

[7] See Kindleberger, p. 134. While Hay argues the possible case for a quota mechanism in terms of favorable price effects for consumers, and while he mentions some reasons that tariffs may be preferred to quotas, p. 691, he does not address the basic efficiency issue involved in choosing between the two policies.

[8] Inefficient producers would likely oppose tariff legislation to replace the quota, because the tariff has the effect of rationalizing production, bringing about the close of the inefficient well.

[9] In an unpublished paper by Mitchell et al., the issue of how final consumer prices are affected by a series of tariff and quota mechanisms in the presence of a domestic monopolist is discussed. This analysis demonstrates that under conditions of domestic monopoly the quota mechanism discussed by Hay turns out to generate the *highest* consumer prices. For a related analysis, see Rachael McCulloch and Harry Johnson.

Import Controls on Foreign Oil: Reply

By George A. Hay*

The position of Ryan Amacher, Robert Tollison, and Thomas Willett (ATW) can be summarized as follows: Assuming that the domestic industry behaves like a profit-maximizing monopoly, if the quota on imported crude oil is replaced by a tariff that is by assumption set so as to achieve the same domestic price of crude oil, the market power of the dominant domestic firms is "severely constrained."

In response I would contend that 1) their assumption about the level of the tariff differs from what I had assumed; 2) their conclusion about the market power of the dominant firms is subject to question; and 3) their assumption about the behavior of the domestic industry is difficult to reconcile with the available data.

The basic issue that I attempted to analyze in the original paper was whether the price of refined oil would be affected, if the quota is replaced by a tariff set so as to permit the same percentage of crude oil imports. ATW, in attempting to rebut my analysis, start by assuming that the tariff will be chosen to lead to the *same price* for domestic crude as a quota system. Had they instead worked with my original assumption, their notion of treating the domestic industry as a monopoly would have led to a more direct comparison with my own conclusion. Still in the monopoly model it is *not* obvious that prorationing will be discontinued. For under the assumption that the tariff will be chosen so as to lead to the same percentage of imports as the quota, the tariff will be raised to ratify any output restriction desired by the domestic industry.[1]

In the light of ATW's assumption that crude oil prices will be the same under either system, their conclusion that under a tariff the market power of the dominant domestic firms is severely constrained is questionable. It is of course true that under the ATW assumption the tariff has the advantage that the real economic cost to this country of acquiring the oil is reduced,[2] with the savings going to domestic producers as producers' surplus, but one would not normally characterize that result as a diminution of market power.[3]

Indeed, judging by the ATW diagrams, the producing industry should *prefer* the tariff, as profits would appear to be substantially higher in a static situation with the "equivalent" tariff. In view of what most observers would regard as a hostile industry position[4] towards the Task Force recommendation of replacing the quota by a tariff, one suspects that ATW have not captured the essence of the situation. My own view, as stated in the original paper, is that the real advantage of tariffs is that, to the extent they are not easily revised upward or are revised only with a lag, the ability of domestic producers to increase price above the *current* level as demand and supply conditions change is sharply curtailed. This indeed represents a diminution of the domestic industry's market power, but one which cannot be conveniently analyzed in a single-period model as ATW have tried to do.

Finally, ATW "make use of the simple model of a profit-maximizing monopoly as a characterization of the domestic oil industry" (p. 1031). My assumption had been that " . . . state regulatory commissions in the large producing areas control output to keep price constant in the face of month-to-month

* Associate professor of economics, Yale University.

[1] This is developed in the Mitchell, Tollison, Tower and Willett manuscript cited by ATW.

[2] Assuming that domestic producers' cost curves accurately reflect the complete social cost of extracting the oil.

[3] The point is that the base price for determining the level of the tariff is the current domestic price. Thus until and unless cost conditions change, the effective domestic price continues to be the monopoly price.

[4] Not limited in my view to what ATW characterize as inefficient producers.

TABLE 1

Year	Average Wellhead Price of Crude Oil (Dollars/Barrel)	Production of Crude Oil (Million Barrels)
1959	$2.90	2575
1960	2.88	2575
1961	2.89	2622
1962	2.90	2676
1963	2.89	2753
1964	2.88	2787
1965	2.86	2849
1966	2.88	3028
1967	2.92	3216
1968	2.94	3330

Source: James Burrows and Thomas Domencich.

shifts in demand" (p. 688). This was not to suggest that the price of crude is in any sense a competitive price; because of prorationing, prices are surely above costs. But for purposes of predicting the response to the substitution of a tariff for the quota, the assumption that the industry will act like a profit-maximizing monopolist may be unrealistic.

An examination of the relevant data proves interesting in this regard. Table 1 lists for the ten-year period preceding the Cabinet Task Force study the yearly average price of crude oil and the corresponding yearly production figures.[5] While it would not be impossible to construct a monopoly model to generate such numbers, my original assumption seems to fit the data sufficiently well to recommend it for the purposes I had in mind.

[5] The price of crude has dramatically increased since 1968, but it is also true that prorationing has been suspended during most of that period. Of course, it must also be noted that import controls on crude were more-or-less abandoned early in 1973.

In Search of the "Wheel of Wealth": On the Origins of Frank Knight's Circular-Flow Diagram

By Don Patinkin*

One of the memories that every former student of Frank Knight undoubtedly carries with him is that of the circular-flow diagram (reproduced on p. 791 of this issue) which Knight used to illustrate the workings of the economic system. To the best of my knowledge, the first appearance of this diagram in Knight's writings was in the mimeographed material that he prepared for teaching purposes at the University of Iowa in the early 1920's.[1] Knight first published the diagram, however, in the four chapters on the economic system that he wrote for the volume of *Readings* prepared for the famous undergraduate Social Science Survey Course at the University of Chicago (Knight 1932). Subsequently, Knight reissued these chapters as a separate booklet entitled *The Economic Organization* (1933), in which form it became a standard feature of his graduate theory course at Chicago over the years. So it was only natural for me to dwell upon this diagram in my memoir on Frank Knight as a teacher which appears elsewhere in this issue.

I had always assumed that this diagram was original to Knight. Thus it came to me as a surprise to notice—in the process of writing this memoir—that Knight himself referred to it as "the familiar figure of the 'wheel of wealth' " (Knight 1933, pp. 60–61). My curiosity aroused, I began a search for the presumably earlier uses of this figure that rendered it so "familiar"—only to discover that the question is not so simple.

Let me first note that though this diagram is concerned with the circular flow of money, Knight used it not in the context of monetary theory, but in order to illustrate certain basic aspects of value theory: namely, the differentiated roles that families and businesses fulfill in the specialization and exchange that characterize a market economy; the ways in which the respective activities of these units are guided by the prices of productive services, on the one hand, and the prices of final goods and services, on the other; and the ways in which the interaction of these two sets of prices enables the economic system to

* Professor of economics, The Hebrew University of Jerusalem. Without burdening him with any responsibility for the conclusions of this note, I would like to express my deepest appreciation and indebtedness to my colleague, Ephraim Kleiman, who encouraged me to write it, and who continued to be the source of many valuable suggestions and criticisms throughout its preparation—including the suggestion for its title! I am also indebted to Paul Samuelson for his stimulating comments on an earlier draft of this note; needless to say, he too does not bear responsibility for its conclusions. I would also like to thank my assistants, Akiva Offenbacher and Reuven Nutkis, for their invaluable help with the detailed examination of the literature on which this note is based—a task which they carried out with gratifying care, accuracy, and responsibility. And my sincerest thanks to Vera Jacobs for her efficient and conscientious typing of this note through its various drafts. Once again, I would like to thank George Stigler for making Knight's unpublished papers available to me, and Glen Gilchrist for providing xeroxes of requested materials from these papers. I am also grateful to Stanley Fischer and Friedrich A. Lutz for providing me with xeroxes of material that was unavailable here. I wish finally to thank the Central Research Fund of the Hebrew University and the Israel Academy of Sciences and Humanities for research grants that made this and other assistance possible.

[1] This is the material that Glen Gilchrist has catalogued under the title "*Economics*, 1920's" and filed in Boxes 8–9 of Knight's papers. Gilchrist has informed me that " . . . most of the material in these boxes is undated, but I have found the date 1926 or 'revised 1926' on a couple of these items as well as a phrase indicating it was used as supplementary material for 'Economics IC' " (personal letter dated April 24, 1973). On the other hand, the bibliography of Knight's works which appears at the beginning of *The Ethics of Competition* (1935, p. 15, bottom) adds the following comment to its listing of Knight (1932): "These four items are an abstract of material mimeographed for private circulation at the University of Iowa during the years 1922–25." I presume that this is the mimeographed material in Boxes 8 and 9, and have accordingly dated this material as 1922–26.

fulfill its basic functions of determining what to produce, how to produce, and how to distribute the product.

As the first step in the search for the sources of this diagram,[2] I examined the standard American textbooks of the period in order to see if in addition to describing the process of specialization and exchange—and the role played by money in facilitating this process—they had also made use of the term wheel of wealth or of the diagram that Knight associated with it. Such an examination of the respective textbooks of Francis A. Walker (1887), Richard T. Ely (1893, 1937), Edwin R. A. Seligman (1905), Irving Fisher (1910, 1912), Frank W. Taussig (rev. ed., 1915) and Fred M. Taylor (1911, 1925) showed that they had not. The same is true of Herbert J. Davenport (1897, 1908, 1913)—to whom, as I have noted in my memoir, Knight had a special affinity. Nor does the term or diagram appear in the textbook by Leverett S. Lyon (1923), which was used at the University of Chicago Business School in the early 1920's. Similarly, no instances of such a term or diagram are to be found in such contemporary British standard works as Alfred Marshall's *Principles* (first ed., 1890; eighth ed., 1920), J. Shield Nicholson (1893–1901), Philip H. Wicksteed (1910; rev. 1933), Edwin Cannan (rev. ed. 1916), and Sydney Chapman (new ed., 1917). Similarly, there is no reference to the term or diagram "wheel of wealth" in Palgrave's *Dictionary of Political Economy* (new ed., 1925). And what lends added significance to the absence of such a diagram from all of these books is the fact that most of them did make use of analytical diagrams in other contexts.

In view of the important influence of the Austrian school on Knight's thinking, I then turned to the Continental literature—only to find that there is no discussion or depiction of the wheel of wealth in the classic works of either Carl Menger (1871), Eugen v. Böhm-Bawerk (1888), or Friedrich v. Wieser (1889). The same is true of the earlier widely used textbook of that leading member of the old historical school, Wilhelm Roscher (13th ed., 1878). Nor does the "wheel" appear in the standard treatises of the turn of the century by Eugen von Philippovich (1897–99) and Adolph Wagner (1892–94, 1907–09), (see fn. 11 below). Similarly, the wheel does not seem to have been referred to in the teaching of economics in Germany in the 1920's.[3] In any event, it does not appear in Gustav Cassel's book (1923, 1932), which was a standard text on the Continent at that time, though Cassel does provide a verbal description of the exchange by consumers of their productive services for goods produced by firms, in what is essentially a barter economy (Cassel 1932, pp. 43–44).[4] I must, however, admit that less significance can be attached to the absence of the wheel-of-wealth diagram from this literature as compared to the Anglo-American in view of the fact that this Continental literature generally did not make use of analytical diagrams in any context.

This consistent failure to find earlier instances of the wheel-of-wealth diagram then raised the possibility that perhaps the search was being conducted in the wrong direction: that perhaps the antecedents of the wheel were to be found not in the economic literature that was concerned primarily with value theory (as is largely the case with the foregoing works), but with that concerned with monetary theory and practice—and with the circular flow of money in particular.

[2] As an aside, I might note that the use of diagrams to describe the exchange of commodities goes back to Aristotle (Theocharis 1961, p. 4). Aristotle, however, used his diagram essentially to illustrate the labor theory of value, and not the circular flow of money and commodities. I am indebted for this reference to my colleague Ephraim Kleiman.

[3] I base this statement on information received from a sample of two: A. L. Gaathon (Gruenbaum) of the Bank of Israel Research Department, who completed his Ph.D. degree at the University of Berlin in 1934; and Freidrich A. Lutz of the Swiss Institute of International Studies in Zurich, who completed his at the University of Tubingen in 1925. Gaathon has also informed me that he has not found any reference to the wheel of wealth in the textbooks by Adolph Weber, Wilhelm Lexis, and Othmar Spann, which were widely used in Germany during the first decades of this century.

[4] Knight (1921–22) wrote a very favorable review article of the first edition of Cassel's book, though without any reference to the point now under discussion.

Such a literature goes back at least to the seventeenth-century mercantilists who (as Jacob Viner has told us) often described the circulation of money as a medium of exchange by means of "... analogies, expecially with the circulation of blood, which William Harvey had discovered not long before" (Viner 1937, p. 37). Even more relevant to our present purpose is Quesnay's *Tableau Economique* (1972 (1758–59), pp. ii–iv),[5] in which the circulation of goods and money among different classes (though not those designated by Knight) is analyzed and illustrated (though not by means of a wheel, and not for the purposes that concerned Knight).[6]

Quite naturally, the circular flow of money was also one of the topics frequently discussed in the quantity-theory literature. Thus in his pioneering work on the quantity-theory equation, Simon Newcomb emphasized that to the "monetary circulation" there corresponded a reverse "industrial circulation" of "wealth or services"—and used the term "societary circulation" to designate the combination of these two opposite circulations (1886, pp. 318–19, 326). Furthermore, Newcomb made use of diagrams (one of which is reproduced in Figure 1a) to illustrate this "societary circulation—and explained that the "arrowheads" which showed the direction of the monetary circulation could "also be considered to represent the industrial circulation, the latter flowing in the opposite direction from that of the arrows, but along the same veins" (1886, pp. 318–19, 326). It is, however, clear from Figure 1a that Newcomb was not concerned with the flows between the basic functional units (families and businesses) that concerned Knight; nor did Newcomb make use of his diagrams to illustrate the organization of production and distribution by the price system.

Much the same statements can be made for the many diagrams (for example, Figure 1b) illustrating the exchange of goods for money under different circumstances that appear in an early Hebrew textbook on money by Vienna- and Berlin-trained Chaim Dov Hurewitz (1900, pp. 105, 112, 119, 150, 153, and 156), which has recently been rediscovered by Ephraim Kleiman (1973). And the same can also be said for the diagram (Figure 1c) showing the opposite circular flows of goods and money that appears in Knut Wicksell's *Lectures on Political Economy* (1901, vol. 1, p. 105; vol. 1, p. 64 of the English translation)—whose purpose, however, is essentially to show how the use of money as a medium of exchange makes the "double coincidence" unnecessary. And in both cases one gets the clear impression that the authors present their diagrams not as original contributions on their part, but as something which they presume to be familiar to their readers from earlier sources—though they do not explicitly indicate what these sources were.[7,8]

[5] See also the passages from the "Extract from the Royal Economic Maxims of M. de Sully" in the *Tableau*, pp. 1–3.

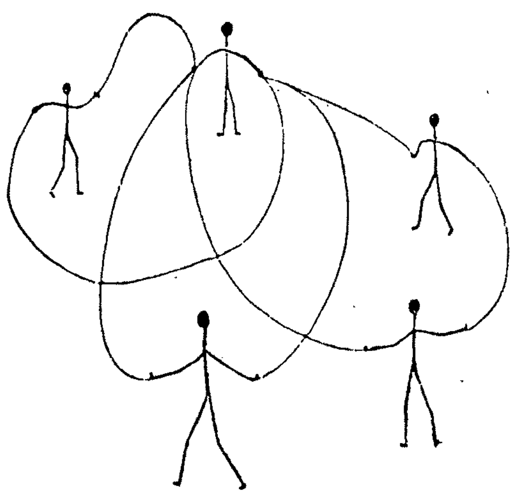
[6] My colleague David Levhari has reminded me of Karl Marx's detailed discussions in *Capital* of his M(oney) = C(ommodity) = M(oney) schema and variations thereof, which stem in part from Quesnay. Marx's various schemata, however, are quite different in both content and purpose from Knight's wheel of wealth. See Marx, v. 1, Part I, ch. 3, especially p. 125; v. 2, Part I, especially p. 113. See also Sweezy (1942, pp. 56–59, 138–45).

[7] In particular, as Kleiman (1973) has emphasized, "Hurewitz did not presume to present new theories, but rather wished to acquaint his readers with some part of what he considered to be the accepted corpus of economic theory." Still, as implausible as it may sound (and it *is* implausible—so that I would welcome counter-examples from the literature), Hurewitz's diagram is the first that I have been able to find that presents the opposite flows of goods and money in the by-now familiar "double-circle" form.

[8] The literature on the circular flow of goods and money has been surveyed by Arthur W. Marget from a somewhat different—and much broader!—viewpoint in the course of his discussion of the history of "The Income Approach to the Theory of Prices" (1938, vol. 1, ch. 12; see also 1942, vol. 2, ch. 7). See also Joseph A. Schumpeter (1912; 1954, ch. 2). Marget (1942, v. 2, pp. 356–57, fn. 18 and 19) also refers to circular-flow diagrams by Francesco Ferrara (1864; 1938, pp. 85, 86, 92) and Fleeming Jenkin (1887, p. 150). All of these diagrams, however, refer not to a money economy, but to the circular flow of goods in a barter economy as a result of barter exchanges of one good for another among the individuals of the economy. Correspondingly, these diagrams are not relevant to the present discussion. Nevertheless, I cannot resist reproducing here Jenkin's

Perhaps Knight, too, considered his diagram to be such a "natural" description of the economic system that he took its familiarity for granted.[9] Still, I would conjecture that Knight's use of his diagram was directly inspired by certain earlier diagrams—though not those of Newcomb and Wicksell which (as already emphasized) only described the role of money as a medium of exchange, and did not depict any of the functional relations that were Knight's main concern. Instead, I think the relevant earlier diagrams were those that appeared in the literature of the first decades of this century that attempted to explain depressions in terms of inadequacies of demand generated by interferences with the circuit flow of money—and that, because of this denial of Say's Law, grew up outside the mainstream of economic thought (though they ultimately led to the development of the money-flow analysis of Copeland (1952) and the flow-of-fund analysis of the Federal Reserve (1955)). Even more specifically, I would conjecture that the direct source of Knight's wheel of wealth was the diagram (Figure 2) showing the circuit flow of money among different functional units that had been used in the foregoing context first by William Foster alone in an article (1922, p. 463), and then by Foster together with his colleague Waddill Catchings in their then widely discussed books on *Money* (1923, p. 305) and *Profits* (1925, p. 255), the latter of which Knight reviewed (1926).[10] I should also note Foster and Catchings' related contention that " . . . money spent in the consumption of commodities is the force that moves all the wheels of industry" (1923,

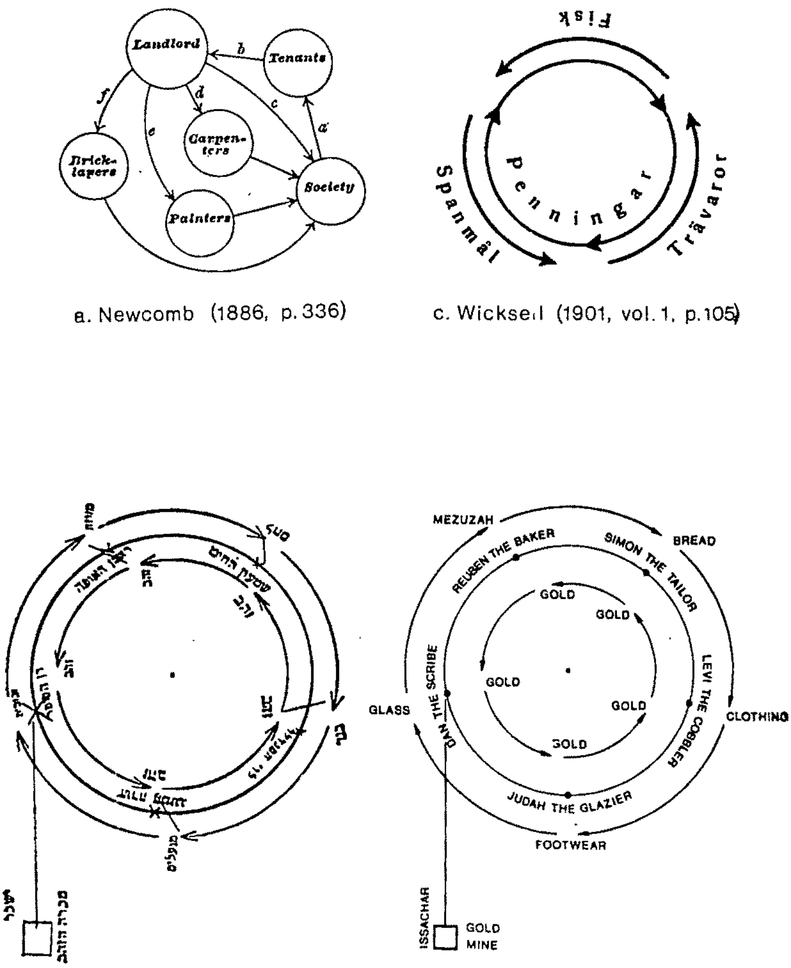
charming diagram illustrating the mutual benefits generated by the trade that takes place " . . . among five little rudimentary people standing upright," where "the lines going out of the strokes to the right indicate produce, which each has to sell . . . [and the] line arriving at his left hand represents the goods which each man consumes" (1887, p. 150–51).



I might also note that unlike Ferrara, Jenkin (who was a professor of electrical engineering) also discussed (though *sans* diagram) the process of trade in a money economy and in this context referred to the "closed circuit (as we might say, borrowing a metaphor from electrical science) . . . round which the sixpence travelled from consumer to producer while the goods went the other way from producer to consumer." (1887, p. 143). The familiarity of such a concept at the time is well-attested by Francis Ysidro Edgeworth's statement (in his biographical sketch of Jenkin (1899 1923, v. 2, p. 47)) that this metaphor "enhances some elementary principles of economics."

[9] Thus see Schumpeter's clear verbal description of some of the basic features of Knight's "wheel of wealth" in his [Schumpeter's] influential article on "Money and the Social Product" (1917/18; 1956, pp. 152–53). I might at this point also cite John R. Commons' observation (1934, p. 294) that " . . . from Quesnay to the Twentieth Century economic theory was dominated, in large part, by his analogy of Circulation of commodities and money. In the latter part of the Nineteenth Century it began to take over the analogy of Turnover. The one is the analogy of a 'flow,' the other of a 'wheel.' " It is not clear from this passage whether Commons actually attributed the use of the term "wheel" to the nineteenth-century literature itself—or whether (as I suspect) this represents Commons' own (and hence post-Knightian) use of the term. Unfortunately, Commons does not provide the references to the nineteenth-century literature that would enable us to check this question. In any event, to the best of my knowledge, Commons himself did not use this term in his earlier writings; see, for example, Commons (1893).

[10] The validity of specifically identifying the origin of Knight's wheel-of-wealth diagram with his review of Foster and Catchings' *Profits* depends, of course, on the assumption that the mimeographed material in which Knight first used this diagram was written in 1926—and I have above (see fn. 1) provided some evidence that this may indeed be the case. But even if Knight wrote this material earlier in the period 1922–26, it could still have been inspired by Foster and Catchings' earlier presentations of the circular-flow diagram—which as indicated in the text, began in 1922. On the intensive discussions—both lay and professional—generated at the time by Foster and Catchings' work, see Dorfman (1959, pp. 339–50).



a. Newcomb (1886, p. 336)

b. Hurewitz (1900, p. 112)

FIGURE 1

p. 277; 1925, p. 234) Thus Foster and Catchings not only presented a diagram showing the opposite flows of money and commodities between the functional units, households and firms, but also connected this diagram with "wheels"—albeit not those of wealth!

Foster and Catchings (1923, p. 303) cite as their source of the diagram the almost identical one by M. C. Rorty (1922, p. 63). Where did Rorty get it? He does not say. But I suspect that it can be traced back to the diagram (see Figure 3) which appears in the work of that "amateur American economist," Nicholas A. L. J. Johannsen, on *A Neglected Point in Connection with Crises* (1908, front matter)—and which has its origin in an earlier diagram by the same author (writing under the name J. J. O. Lahn) in a work entitled *Der Kreislauf des Geldes* (1903).[11] For though Johannsen was

[11] I am indebted to Friedrich Lutz for bringing "Lahn's" diagram to my attention. Marget (1938, vol. 1, pp. 331–36) discusses the intellectual influences that Johannsen and Adolph Wagner exerted one on the other. Whatever the nature of these influences, it is clear that Johannsen did not derive his diagram from Wagner: for, as noted above, Wagner made no use of diagrams in his analysis in general—and this is true of his analysis of money-flows in particular (1909, pp. 158 ff.).

JOHANNSENS' DIAGRAM

FIGURE 3

neglected by most of the profession, his contributions were appreciated by Wesley C. Mitchell (Dorfman 1949, p. 413)[12]—who in 1920 became Director of the National Bureau of Economic Research, and to whom (among others) Rorty (who was then President of the Bureau)[13] expresses his general indebtedness.

Let me conclude with two comments. First, even if the source of Knight's "wheel of wealth" was Foster and Catchings' diagram, it must be emphasized that Knight adapted this diagram to completely different purposes. In particular, as indicated at the beginning of this note, Knight's concern was with the allocative functions of the price system under the implicit assumption of full employment, not with the possible generation of unemployment as a result of inadequacies of aggregate demand. Thus no matter what the origins of Knight's wheel of wealth as a diagram, its use to illustrate

[12] See also Mitchell's references to both Johannsen and Rorty as listed in the indices to his classic works on the business cycle (1913, 1927)

[13] See title page of Rorty's book.

basic aspects of price theory—as distinct from monetary theory—seems to have been original to him.[14]

Second, after having in this way built conjecture upon conjecture in the search for the "familiar figure" that inspired Knight's wheel-of-wealth diagram, I must—as something of an anticlimax—note the possibility that Knight never drew his inspiration from any such figure in the first place! For in the earlier mimeographed version (1922–1926) of his analysis of the functions of the price system that I referred to at the beginning of this note, Knight starts his discussion with the statement that "... the general character of an enterprise organization reduced to its very simplest terms can be indicated by a diagram which suggests the familiar figure of speech, the 'wheel of wealth'." Thus from this passage it would seem that the inspiration for Knight's wheel of wealth diagram originally came not from a "figure," but from a "figure of speech"—and that Knight actually developed his diagram independently of the earlier ones described above.

[14] In this connection it is interesting to note the different uses that Samuelson has made of circular-flow diagrams in his *Economics: An Introductory Analysis*—the textbook by means of which Knight's wheel of wealth has become familiar to a modern generation of economists. (On the origins of Samuelson's diagram in Knight's teachings, see above fn. 8.) All editions of Samuelson's textbook present a minor adaptation of Knight's description of the functions of the economic system in terms of "what, how, and for whom" to produce. But in the first three editions this discussion is not accompanied by Knight's wheel of wealth. Instead, Samuelson uses the circular-flow diagram in these editions only for the quite different purpose (to which Knight had also very briefly adverted (1933, p. 62)) of illustrating the equality between national income and national product (Samuelson 1948, p. 206; 1951, p. 231; and all subsequent editions up to the most recent—1970, p. 170). Only in the fourth (1958, p. 41) and later (e.g., 1970, p. 42) editions is Samuelson's discussion of the functions of the economic system illustrated by Knight's "wheel of wealth," somewhat modified. In these editions Samuelson also makes use of the wheel in order to provide a detailed illustration of the simultaneous, mutual determination of prices in a general-equilibrium framework (1955, p. 597; 1958, p. 615; 1970, p. 607). Thus beginning with the fourth edition of *Economics*, Samuelson presents the wheel-of-wealth diagram at three different points in his textbook, each time in a somewhat different context.

But once again things are not so simple: for neither the *Oxford English Dictionary* nor any of the other standard reference works I have consulted list such a figure of speech. "Wheel of fortune," yes; "wheels of industry," yes; but not "wheel of wealth." Did Knight later delete the words "of speech" from the 1932 version of his discussion because he became aware of this fact? Or was this deletion the result of a slip of the pen or typographical error? Or did a slip occur in the original memeographed version in the very insertion of the words "of speech"? I do not know.

IN MEMORIAM

FRANK H. KNIGHT

1885–1972

Frank Hyneman Knight was born in White Oak Township of McLean County, Illinois, on November 7, 1885, and died in Chicago on April 15, 1972. He was the oldest of eleven children, of whom nine survived infancy and two (Melvin Moses, of Berkeley and Bruce Winton, of Dartmouth) also became professors of economics.

Knight's early career seems almost aimless in retrospect (and he was fond of saying that he abandoned farming chiefly because his feet hurt). He attended high school in Lexington, Illinois (1903–05), American University in Harriman, Tennessee (1905–07), was a stenographer at the Jamestown Exposition in Norfolk, Virginia (1906–08), attended Milligan College in Tennessee (1908–11, Ph.B. 1911), then University of Tennessee, 1911–13 (B.S., M.A. 1913), where he was an assistant in chemistry, and wrote a master's essay on "Gerhard Hauptmann as an Idealist," and finally Cornell University (1913–16; Ph.D. 1916). He was an excellent student (even in deportment, in which he received 100 each year at Milligan!), but not free of skepticism from his earliest years. In his autobiography (*Pioneer's Progress*, 1952), Alvin Johnson reminisced about Cornell days:

> Knight came up from Tennessee, where border-state diet had endowed him with dyspepsia and a graven expression of pessimism. He was majoring in philosophy under Creighton and Thilly and doing a minor with me. I found him the keenest student of theory I had ever had. When I was elaborating some theoretical subtlety he would turn on me the gray light of his skeptical eyes, seeming to say, "I don't believe a word of that." Sometimes he would attack my position, very competently. I liked that. It was stimulating to wrestle over points of theory.
>
> One day in the spring Knight came to me with an unusually sad face. "Doctor," he said, "I thought all along I was doing pretty well in my philosophy major. But Creighton called me in and gave me the most frightful hauling over the coals. Said I was totally unfit to study or teach philosophy; indeed, that I ought to drop the idea of teaching anything, for with my attitude I'd do more harm than good. I went to Thilly for comfort, and he gave it to me still worse."
>
> I was astonished. Could two such clear-headed philosophers make such a mistake about so promising a student as Knight? I couldn't believe it, I went straight to Creighton.
>
> "Knight?" he said bitterly. "It isn't that he is devoid of ability. But with his ingrained skepticism he repudiates all the values of philosophy. As a teacher or writer he will be not just the blind leading the blind into pitfalls. He will destroy the true philosophic spirit wherever he touches it."
>
> "I see," I said. "Knight has been miscast. He should not have majored in philosophy, where his work and attitude are so unsatisfactory, but in economics, where he does excellent work. Suppose I take him over?"
>
> "Do as you please," said Creighton acidly. "We in philosophy will have nothing to do with him."

The years 1913–16 marked the rapid mastery of economic theory. In the former year, Knight had essentially no knowledge of the subject; in the latter year he had completed *Risk, Uncertainty, and Profit* (with the title, *Cost, Value, and Profit*), one of the most influential doctoral dissertations in the history of American economics. With revisions, it won second prize in the then-annual competition of economics, the Hart-Schaffner-Marx prize for 1917 (the first prize was won by E. E. Lincoln, *The Results of Municipal*

Electric Lighting in Massachusetts), and it was published in 1921. The depth of the knowledge of economic theory that Knight acquired in these few years is simply incredible.

After a year as instructor at Cornell, Knight moved to the same post at Chicago (1917–19), and then became an assistant professor and (after 1922) professor at Iowa. He resigned from Iowa in 1928, and spent the rest of his life at the University of Chicago. He became emeritus in 1955 but continued to teach until 1958.

He married Minerva Shelburne in 1911, and they had three daughters and one son. They were divorced in 1928. In 1929, Knight married Ethel Verry and they had two sons.

Risk, Uncertainty, and Profit was not only Knight's first systematic treatise, but also his last. This remarkable work which was reprinted many times in the London School series, not only influenced the thinking on risk and profit of a generation of economists but also served as one of the major treatises in graduate courses on economic theory. The following decade was filled with articles of the highest distinction—most of the best of them included in *The Ethics of Competition* (1936). The essay on the nature of cost, directed to Pigou's famous error on increasing cost industries, is perhaps the most lasting. In the 1930's, his interests in economics shifted to capital theory, and his famous debate with the Austrians (Machlup and Hayek, and the temporary Austrian, Kaldor) covered the decade.

Beginning in the 1930's, however, his main interests began to shift from economic theory to social philosophy: the nature of public discussion and decision making; the content (or absence thereof) of religious ethical systems; the contradictions in democratic planning. A profound distrust of democratic politics (which reached its climax in the dark days of 1932, when he delivered his lectures on "The Case for Communism") was joined to an even more profound fear and dislike of all authoritarian systems: Knight was deeply pessimistic on the rationality of all political processes.

Frank Knight was one of the last prominent economists to avoid all significant connections with the political and business worlds. Even the presidency of the American Economic Association, nomination to which he declined for 1937 and 1938, was complimented as burdensome and criticized as diversionary, although he was persuaded to accept the office in 1950. He received the Francis A. Walker Medal in 1957. For many years he served as coeditor with Jacob Viner of the *Journal of Political Economy*. The impressions made by his highly idiosyncratic teaching have been discussed by two former students (Stigler, *JPE*, May–June 1973; Patinkin, this *Review*). For a full generation he was the dominant intellectual influence upon students at the University of Chicago, and in general his influence was most profound upon the most able students. A reasonably complete bibliography through 1936 is contained in *The Ethics of Competition*. Two other extensive collections of his essays are *Freedom and Reform* (1947) and *History and Method of Economics* (1956). He translated Max Weber's *General Economic History* (1927), and wrote with T. W. Merriam, *The Economic Order and Religion* (1945).

Combatting Role Prejudice and Sex Discrimination

Findings of the American Economic Association Committee on the Status of Women in the Economics Profession*

I. Role Prejudice as an Economic Problem[1]

It is well recognized among economists that arbitrary discrimination in the labor market creates a general economic loss. Where certain people are excluded from jobs for reasons which have nothing to do with the performance of the jobs themselves, the loss to consumers plus the loss to those who are excluded is greater than any gain to those who are favored. There is now copious literature on this subject.

It is less well recognized that discrimination among existing members of the labor force is only a special case of a much larger process of role learning and role acceptance, which begins almost from the moment of birth. It is not merely that differences in skills are learned, as in Adam Smith's famous passage about the porter and the philosopher,[2] but images of possible roles on the part of both the role occupants and the role demanders are likewise learned in the long process of socialization. The existing division of labor at any one time, therefore, may reflect "role prejudice"—that is, a learning process by which certain irrelevant biological or genetic characteristics of individuals are associated with certain roles. Some genetic distinctions are significant for role performance, but many are not and yet are widely believed to be significant. These beliefs are products of a false social learning process, which can be a source of economic loss even larger than false discrimination within an existing labor force. Discrimination in an existing labor force indeed emerges as one consequence of the much larger process of the development of role prejudice.

Role prejudice tends to develop when there are genetic differences in the human population which are visible but are not necessarily significant for role performance. We see this clearly by considering those genetic differences which are undetectable except by refined methods and therefore are socially invisible. Some of the blood types are perhaps an example. In ordinary life we are quite unaware of a person's blood type. Consequently, it can be safely assumed that there is no role prejudice against blood types of different kinds, unless these happen to be associated with other characteristics which are socially visible. For the major types, this association is fairly minimal. Consequently, we would be very surprised to find a distribution of blood types in any occupational group or income group of any size which is markedly different from the distribution of blood types in the population as a whole.

For any particular distribution of genetic characteristics, it is clear that we can postulate "no-prejudice proportions" in all the different occupations and structures of society. In the case of the socially invisible and irrelevant characteristics mentioned above, the no-prejudice proportions, subject to random variation, in any group of society would be expected to be the same as the proportion of the characteristic in the society as a whole. If there were any case—and I must confess I have not been able to think of one—of a genetic characteristic which is relevant to role performance but which is socially in-

* This report is published pursuant to a resolution adopted by the members at the Annual Meeting of the American Economic Association, December 28, 1971. In providing for establishment of the Committee on the Status of Women in the Economics Profession, the resolution specified that "Its general findings, conclusions, and recommendations shall be published by the American Economic Association upon the Committee's request" (*Amer. Econ. Rev. Proc.*, May 1972, p. 474). This report has not been considered or approved by either the Executive Committee or the membership.

[1] Part I was drafted for the Committee by Kenneth E. Boulding, professor of economics, University of Colorado.

[2] "The difference between the most dissimilar characters, between a philosopher and a common street porter, for example, seems to arise not so much from nature, as from habit, custom, and education" (p. 15) Adam Smith.

visible and not in the information system, then the existing structure of proportions of the characteristic in different occupations might not be the same as the proportions in society as a whole, and those occupations which this invisible characteristic favored would have a larger proportion than in the society as a whole, but this would still constitute a no-prejudice distribution. Paradoxically enough, without knowledge there can be no prejudice; without some knowledge, there can be no false knowledge.

Role prejudice may easily arise where there are highly visible and observable genetic characteristics, such as sex, race, height, size, color, and so on. Historically these have frequently been perceived as having some relevance to performance in different roles. But this relevance tends to be exaggerated, because a rational tendency to economize information can easily turn into an irrational process of stereotyping and false knowledge.

The genetic division of the human race into men and women qualifies in most societies as the major form both of discrimination in the existing labor force and of role prejudice. This is not surprising, as the genetic difference between the sexes is far greater than it is among the races in terms of the structure of information of the genetic code. There is one role indeed—that of bearing children—in which there is 100 percent genetic specialization between the sexes, in the sense that no men will be found in the child-bearing population. The very social visibility of the distinction between the sexes, however, makes it a prime candidate for role prejudice, which creates a huge reservoir of false knowledge, false education, and false learning processes. All are costly to society in exactly the same sense that an unknown and unutilized natural resource is costly in the sense of opportunity foregone. We can, oddly enough, think of role prejudice as a large natural resource which can be mined by the development of true knowledge and better learning processes to the benefit of the whole society.

Where the sex distinction is completely irrelevant to role performance, role prejudice can be said to exist wherever there are substantial deviations from the 50 percent rule —that is, 50 percent of each sex in the occupation—this being assumed to be the proportion of the sexes in the total society. The difficult case, of course, is where there is some genetic foundation for partial role differentiation. It is the cases between the 50 percent and 100 percent that are difficult, and in these cases there is often no information system—at the moment at any rate—which can inform us as to the exact proportion of the sexes in different occupations which constitutes zero role prejudice. Fortunately, however, we do not have to know where the exact position of the ideal proportion is if the existing proportion clearly represents a gross disproportion. In order to set up a social policy we do not have to know exactly where the ideal lies. We merely have to identify those cases in which the deviation from the ideal is so clear and striking that we can find wide agreement as to the desirable direction of change. At the bottom of the mountain, one knows which way is up, even though one may not know exactly where the top of the mountain lies. Maximizing is an illusion, but betterment is not.

It is the contention of the American Economic Association Committee on the Status of Women in the Economics Profession (the Committee) that there is gross disproportionality in the proportion of women to men in the economics profession, and especially in university teaching, as revealed in the data which have been collected. Fortunately, we do not have to argue whether the genetic differences between women and men would result in a no-prejudice proportion of women in economics of 40 percent or 50 percent or 60 percent when the actual proportion is less than 10 percent. This gross disproportionality, of course, arises from sources in the long history of the human race, most of which are outside the economics profession. This, however, does not excuse the economics profession from setting in motion processes which will raise its proportion of women. We are a sector of the knowledge industry and a group of people concerned with eliminating sources of unnecessary economic loss. Only if we are successful beyond our wildest expectations, considering the vastness of the mine of ig-

norance and false learning, will it be necessary to raise the question as to whether we have gone too far.

The critical question, therefore, is that of the "betterment production function," as it might be called. The social indicator of betterment is in this case clearly an increase in the proportion of women in the profession, especially in those branches where the proportion is least. If the rate of change of this proportion is regarded as the product, the question is: What are the inputs which produce this output, and particularly, what are those inputs that can be most easily expanded and that have the highest marginal productivity? We might also look at those inputs which have a high negative marginal productivity and which can be contracted. Four broad classes of inputs may be named: Information, Persuasion, Rewards, and Punishments.

1. *Information*

Information properly organized changes the images of the world of people who receive it and consequently changes their behavior. There are two aspects of the information process— theoretical structures and information about fact. Better theoretical structures are an essential ingredient in the advancement of knowledge, and in this particular case it is important that the theory of role prejudice, as outlined above, should be widely recognized as a legitimate extension of economic and social theory. One of the greatest enemies of the fact of prejudice is the spread of the idea of prejudice. Once it is recognized as a theoretical construct, the facts of perverse social learning which previously have been invisible become glaringly visible. The improvement and elaboration in detail of the theory of role prejudice is still an important task for the future.

Coupled with a wider appreciation of the theory, the development of statistical information, case studies, and a continuing series of social indicators can serve as a constant criticism of what is false in existing theories of the world and a reinforcement of what is true. It is tempting to think of every advance in knowledge as the result of a combination of new theoretical insights with new information collection and processing procedures. In social systems, however, knowledge does not merely reflect the world—it changes it. And in this case particularly, the more we know about role prejudice, the less there is likely to be. Getting lost is one way to improve one's knowledge of the terrain, but studying a map is a better way, and diminishes the amount of getting lost.

2. *Persuasion*

The mere existence of knowledge and information is not always enough to insure its spread. One of the major sources of ignorance is inattention, and to insure the spread of new knowledge it is often necessary to call it to the attention of people in ways which are dramatic and persuasive. The fact that persuasion can be abused to propagate false knowledge does not excuse us from its proper use in the propagation of truth. Persuasion plays a particularly important role in the change of values, and without getting into the ancient controversy about the truth of values one has to recognize that change in our image of the world inevitably changes our values about it. As scientists, we have to guard against the information filter which our values create. We cannot pretend, however, that information is value free. Change in knowledge and change in values are joint products of a single process.

A problem of particular difficulty is that of irrelevant and unconscious sources and attitudes, even in the academic and intellectual community, which is supposed to be on its guard against irrationality. The relations between the sexes are often characterized by high levels of emotion, and hence are particularly subject to the distortions which arise from unconscious or irrelevant sources. It is one of the functions of ethical persuasion to raise our awareness and to set up defenses against attitudes and prejudices which arise from this source.

3. *Rewards*

It is widely recognized in the learning process that positive and negative payoffs are of great importance. Every economist is familiar with the proposition that any human activity which is rewarded above some

neutral level will expand and those rewarded below this level will contract. The structure of knowledge and values in the human mind, likewise, grows towards its own more positive payoffs and away from the less positive and negative payoffs. It is by constructing a reward structure that society is most likely to achieve change. These rewards may be either internal or external. Our own applause, as Paul Samuelson suggested, may indeed be the greatest reward of all. No economist, however, can deny the significance of external reward, whether the applause of others or those more tangible things, such as subsidies, tax remissions, and price changes. Curiously enough, although psychologists seem to agree that rewards are more successful than punishments in the learning process, it seems harder to legitimate a reward structure. A suggestion, for instance, that dues paid by members of the American Economic Association should be scaled down if the organization or department to which they belong had a high proportion of women might be hard to legitimate, even though it might be effective. Nevertheless, the search for reward structures should go on.

4. *Sanctions and Punishments*

Punishments always seem to have been easier to legitimate than rewards, perhaps because of a belief that they are cheaper, in spite of much evidence that they do not contribute as much to learning. Nevertheless, there is one extremely good reason for the use of sanctions. In the case of public goods and public bads it is well recognized by economists that legitimated threat of some kind is essential if we are to avoid some "tragedy of the commons." Private reward structures, such as the market and the price-profit mechanism, are particularly well adapted to the provision of private goods, but are poorly adapted to public goods, where without some sanctions in the collection of taxes public goods would simply not be provided in adequate amount. Private reward systems are also poorly adapted to dealing with public bads such as pollution, of which role prejudice is a prime example, in the sense that everybody is somewhat diminished by it. The "freeloading principle" applies here, for if there are no sanctions it will pay the individual not to participate in a collective sacrifice required for the increase of a public good or the diminution of a public bad. To rely on purely private rewards and exhortations for the diminution of role prejudice is rather like trying to finance a government with purely voluntary contributions.

To say that sanctions are necessary does not mean to deny that there are acute problems both in the quantity and the quality of sanctions, and that bad sanctions may be worse than no sanctions. This, however, does not excuse us from the search for good sanctions, which must not be larger than necessary, must be credible, legitimate, precise, equitable, and so on. Sanctions should fall on violators and not on the innocent; they should be appropriate—that is, any punishment should fit the crime—and it should be recognized that, like all deterrents, punishments are most successful when they are not carried out. Economists will recognize, however, that no system of sanctions can be perfect and that there has to be some kind of tradeoff between imperfection in the system of sanctions which will inevitably lead to some failures of both justice and of deterrence, and the failure of the provision of public goods or the elimination of public bads which too weak a system of sanctions might involve.

The power of the American Economic Association to invoke sanctions is small indeed, and it could be argued that, apart from publicity—which under some circumstances is itself a sanction—a professional association should not legitimately engage even in linguistic sanctions like censure. Nevertheless, it is only realistic to be aware of the fact that sanctions of government can be invoked by groups in the society in the furtherance of what they believe to be general betterment. Even a profession is not exempt from participating in the society of which it is a part. It is important that vigilance be maintained against both the abuses of sanctions and their undue neglect, even though the primary

emphasis of the intellectual community is properly on information, persuasion, and rewards.

The Committee is aware that it has a special task which is part of a much larger social process. Role prejudice in particular is by no means confined to women. Men also suffer from role prejudice, and it accounts for other kinds of discrimination than one based solely on sex. Nevertheless, as economists we believe in the division of labor and we believe that the pursuit of our particular task is to complement rather than compete with the labors of others in the long process of social betterment. The guidelines that we are proposing, while they are particularly applicable to our special case, are all simply examples of the fundamental general principle—that where there is clearly not enough, the simplest and most necessary guideline is "more." In what follows we spell out in detail this essential principle.

II. Guidelines to Obviate Role Prejudice and Sex Discrimination[3]

The following guidelines are written for members of the American Economic Association who, as faculty members in departments of economics in various colleges and universities, as economists in business, industry, or government, wish to remove, mitigate, or prevent discrimination against women economists. These suggestions have been prepared by the Committee to illustrate steps that can be taken by those of good will who seek to comply with the spirit as well as the letter of laws proscribing employment discrimination. Over time, other suggestions may be appropriate; and the guidelines may need amendment or modification to reflect changes in the conditions of employment faced by women economists.

Not all institutions will wish to implement all the recommendations given here. Nevertheless, thoughtful consideration of whether a particular suggestion has merit for a given institution may reveal needs heretofore unrecognized and may be the basis for setting in motion policies that will eliminate sources of discrimination and unnecessary economic loss.

Because many members of the American Economic Association will wish to review again the resolutions relating to elimination of sex discrimination among economists that were passed by the Association at the annual meeting in December 1971 at New Orleans, the resolutions are repeated here.[4] They provide the framework for the Committee's guidelines for positive policies and remedial action to obviate role prejudice directed against women economists.

> I. RESOLVED that the American Economic Association declares that economics is not exclusively a man's field. The Association herewith adopts a positive program to eliminate sex discrimination among economists, whether employed in universities and colleges, industry, finance, publishing, or other endeavors. The President shall make known, by all available means, the Association's adoption of the following principles:
>
> a) To redress the present low representation of women in the economics profession, the Association shall actively encourage the study of economics by women at all levels of education.

Low representation of women in the economics profession occurs in part because women students do not have appropriate role models at the university nor in visible positions in other places of employment. Women also lack accurate information and encouragement throughout the entire educational process. The role models needed are professional women economists with whom young women can identify and from whom young women can obtain information and counseling. It is also important that young men in the classroom recognize, as a matter of course, that professional women play a vital

[3] Part II was written by Barbara B. Reagan, professor of economics, Southern Methodist University, on behalf of the Committee. These guidelines reflect the input and discussion of all Committee members as well as public discussion in Toronto at the December 1972 meetings of the American Economic Association.

[4] The resolutions are contained in the Appendix to the minutes of the annual meeting, pp. 473–74.

role in economics as well as other fields, and that professional competence among adults should not be sex-related. Throughout their entire training, children, both boys and girls, should have opportunities to appreciate the economic contribution of women to our society, and the economic circumstances of discrimination against women. By the time young women have completed high school, they should know that job planning is essential for everyone and should understand that economics is a perfectly appropriate field of study for women.

There are numerous things that economists can do to encourage the changes needed to overcome previous false social learning.

(1) *Educational Institutions.* The value of women faculty role models at the college or university level cannot be stressed too much. A substantial amount of talent that would otherwise flow into this profession is lost because, without the presence of women faculty, undergraduate women erroneously assume that economics is a profession for men only. An exclusively male department also lacks the abilities to correct these impressions, not least because men economists themselves overlook the difficulties subsumed under the cliché "economics is a man's field." A women economist can provide encouragement and proof that it is possible not only to survive but to accomplish, even as a member of a tiny minority group. The positive role that women faculty can play in enhancing the education of both women and men should be considered in making appointment decisions.[5]

Departments should also use other methods of making women more visible—inviting guest lecturers (for example, women from government, industry, management, finance, public action programs, research), hiring women visiting professors, featuring women in career opportunity conferences, using women as special lecturers, recommending women experts when students want someone with whom to consult, and including women economists in informal gatherings of economists. Again, these are ways of doing away with role prejudice.

Departments should facilitate communication between senior women economics majors and freshmen women so that the latter may be appropriately informed and encouraged to study economics. Whenever possible, communication between women graduate economics students and women undergraduate majors should be similarly facilitated.

(2) *Government.* Part of the lack of role models for potential women economists has arisen because the government at all levels has put little effort into appointing women economists to highly visible positions. Economists should work to increase the number of women economists in high ranking positions in the federal and state governments to serve as examples and encouragement to women facing career decisions.

The federal government, as part of the Federal Women's Program, should require that women be given equal opportunity in government-financed graduate student programs and should encourage women in such programs to study economics.

(3) *Private Industry.* Private industry should search for women economists in order to place them in both research and administrative positions. The reciprocal employment relationships between industries and universities (and/or consulting arrangements) should be encouraged for women economists as it has been for men.

Training of mid-career women economists already employed in the private sector should be encouraged. Both full- and part-time training and educational opportunities should be made available to women economists, as to men, to enable them to acquire new skills and improve their status

Resolution Ib) No academic institution or department shall discriminate against

[5] Elizabeth Tidball has established a correlation between the number of women faculty at a school and the number of women students who subsequently attain recognition for their achievements, using a random selection of listings in *Who's Who of American Women* for a three-decade period. The statistically significant positive correlation coefficient was $+0.953$ with $P<0.005$. By contrast, "the number of men faculty neither enhanced nor detracted from the output of women achievers."

women in admission to studies in economics or in the form or amount of financial aid. Every economics department shall actively encourage qualified women graduate students without regard to age, marital or family status, and shall actively promote their subsequent employment.

(1) *Admissions.* The admissions process should be checked by economics departments to ensure that there is no discrimination on the basis of sex, age, marital, or family status. In efforts to eliminate or preclude such discrimination, whenever possible, women faculty or graduate students should participate in the admissions process. When prospective candidates for admission are interviewed, women applicants should not be asked questions about marital or family status (actual or prospective) that are not asked of men.

(2) *Recruitment.* Because the applicant pool is often low, departments of economics should actively recruit women into their programs at both the graduate and undergraduate levels. Women graduates of the department form a good supplement to such recruiting efforts. To give evidence of career opportunities, departments might keep a file of letters from former economics majors on their experiences with further academic training and/or the labor market. Whenever possible, women graduates from the department should be invited back to give lectures. When recruiting graduate students, particular attention should be paid to institutions from which large numbers of qualified women may be recruited; such places may include state and city colleges and women's colleges. Letters to colleagues teaching undergraduates should publicize the department's interest in women applicants. When considering applications, women with undergraduate preparations that are closely related to economics should also be considered.

(3) *Financial Aid.* When faculty members or department chairmen are making decisions with respect to the size of grants or fellowship aid for various graduate students, marital status should have no relevance. In particular, married women should be treated in the same way as married men. Under no circumstances should it be assumed that a married woman's needs are less than a man's without due consideration of the financial facts involved.[6]

Information on sources of fellowships and grants should be distributed so that all students, both men and women, receive the information on an equal basis. When departments are asked to make nominations for financial aid, qualified women should be included.

Federal scholarship and loan programs should actively seek out women graduate students as potential recipients and should inform all departments of their interest in women applicants.

(4) *Encouragement in the Program.* Those departments that at present have no women faculty members should make special efforts to schedule guest lectures by women economists so that graduate students will be more aware of the active participation of women in the field. Faculty should include publications of women economists on reading lists, particularly in basic courses.

(5) *Placement.*[7] In writing recommendations for prospective employment, econo-

[6] A relevant court case in 1971 involved John and Mary:

"... high school sweethearts who married shortly after graduation. Mary went to work for a bank in a small city in Northern Indiana. John worked as a salesman in the same city. Mary prospered, was promoted, and eventually became a cashier. John did less well. Growing restless, he enrolled in college, using Mary's earnings as the basis of his support. Eventually he graduated with a Master of Science degree in Science Education and entered the teaching profession. In college, and after graduation, reportedly because of college experiences, John claims that he grew intellectually and socially while his wife stagnated. Finding Jane, a fellow teacher, more compatible, he fell in love and pursued an affair with her. Mary sued for divorce and claimed as part of her settlement the present value of the college education of her 41 year old male Caucasian husband, the value of which was computed at $49,653. In the face of this suit John saw Mary in a new light. They were reconciled."

(This information was provided to the Committee by David R. Witmer, Assistant Chancellor, University of Wisconsin-La Crosse.)

[7] Although these comments are written with respect to recommendations for and placement of women graduate students, they apply equally to placement of women economists in subsequent stages of their careers.

mists should not include comments on physical appearance; such comments are not relevant in evaluation of a candidate's qualifications for employment. In particular, care should be taken that comments on physical appearance are not used differentially in evaluating female and male applicants. References to so-called "feminine" or "masculine" traits should be omitted. Marital status, number of children and other private facts of a candidate's life should not be assumed to affect a person's ability to meet professional obligations. Comments regarding political views, particularly the Woman's Liberation Movement, are appropriate only insofar as they are relevant to the applicant's field of research or scholarship.

Care should be taken not to use traditional sex-related stereotypes—downgrading women for conforming to the "passive-accepting" model, or condemning women as unduly "aggressive" for competing to a degree well within the bounds of normal behavior set by their male colleagues for themselves. The latter type of participation may seem unduly aggressive only when measured against a passive, accepting stereotype of the feminine role, but not when measured against professional standards.[8]

Resolution Ic) No employer, academic or otherwise, may discriminate against qualified women economists as candidates for positions, or for promotion or tenure, or for assignment of duties and responsibilities.

Employers should actively recruit women for the economics staff so as to increase diversity—sex as well as race, field or specialty, and school of training. Evaluation of employees' performance and potential for advancement should be based on the same criteria for women as for men. Assumptions about availability for employment as economists should not be made on the grounds of marital status, other employment, home obligations, or the like.[9] Women faculty members should share equally in administrative and committee appointments. Temporary positions or consultantships should not be used for women as a subterfuge to avoid naming them to permanent positions. Titles such as lecturer or adjunct should not be used to deny tenure track positions. Similarly, in government and industry separate job classifications should not be used as a subterfuge masking discrimination against qualified women economists.

All women should have access to management and executive training courses. In-service training opportunities, "acting" administrative positions, and other forms of "grooming" for advancement should be made available for women as well as for men. Informal benefits, as for example, travel reimbursement, conference invitations, and speaking opportunites should be equitably apportioned. Government agencies should submit evidence to the Civil Service Commission that women are being included in these activities. Follow-up evaluations of training courses should include information as to whether women participants in such training courses move ahead in their jobs as rapidly as men.

Members of the American Economic As-

[8] "Women candidates, to win entire approval, have to be both chic and brilliant, and so the woman who is plain-looking, a spinster-scholar type, evokes a negative response for she is not a complete woman, she lacks sociability and will not flatter the egos of male department members. Dossier after dossier divulges irrelevant, negative commentary: '—is a large, broad-boned, somewhat awkward young woman who must be close to six feet in height,' 'her mousiness belies a sharp mind'; '—is . . . tall and proportioned like an Olympic swimmer'; 'she is a steady woman who will never marry.' And within a single paragraph from a male at an elite graduate school; she has a 'comfortably upholstered' person and personality, she performed 'athletically' in a particular course, she would be the 'wheelhorse' of any committee on which she served. And of an older woman, 'if she has any faults, they are those that usually accompany the ambitious woman of her age.' In other words, the rare comment on a male's appearance is simply a footnote, the frequent comment on a female's, a thesis statement." . . . "Our experience of women's dossiers confirms that a letter writer, often unselfconsciously, diminishes a female candidate's intellectual power by stereotyping her as too feminine, too pretty. These comments, a composite from a type candidate's dossier, make a damning package: sweet, but not saccharine, quiet, unaggressive, shy, but very pretty, a decoration to the classroom." [M.L.A. Newsletter, p. 3]

[9] ". . . the employment form of a major oil company included the question, 'can this employee relocate?' On examining the completed forms of 300 women employees, the company officials found the appropriate box marked 'no' in every case. On probing further, they discovered that no one had actually asked the women whether they would relocate; it had simply been assumed that they would not." [Boyle; p. 94]

sociation should review written and unwritten membership criteria of local or regional economics associations to ensure that women economists enjoy equal access and equal opportunity for participation. Members of the Association can be effective in protesting the exclusion of women from membership in any local economic association or any *other professional organization* to which they belong that is not willing to invite women economists to be members. Membership in such organizations is an important part of the informal professional network, and denying women access to any part of the network is sex discrimination.[10]

Positive efforts to regularly include women economists in the informal professional network should be conscientiously encouraged by all. The inclusion of women in this network should be considered a matter of routine operating procedures.[11]

Resolution Id) Salaries, fringe benefits, and facilities and resources for research for women shall be the same as those for men in the same position and rank.

All employers should regularly compare the salary, training, fringe benefits, and other terms and conditions of employment for women economists with those for male economists with comparable education and experience. Where women have not received treatment similar to that given men, corrective action should be taken immediately. Remedies may include giving the woman assistance with "upgrading" herself through leaves or other devices, changing rank or position, increasing base pay and granting back pay. (That back pay should be accompanied with interest may seem an ideal to some professionals, but scarcely to economists.) Rectifying a previous inequity can in no way be construed as reverse discrimination. Indeed, the aim of the action normally has to be to change the initial distribution of emoluments in favor of the party subjected to discrimination. By definition, at least the relative shares of all other groups must decline. There is no other way to correct unfair shares. What happens to absolute shares obviously depends on what's happening to the size of the pie.

After corrective action is taken, care must be exercised that equal treatment is maintained in the future. It is very easy to recognize that an equity raise has been given a women, and then during the following years to slip into old patterns of thought so that merit raises gravitate to men in the department, thus reestablishing old patterns.

(1) *Salaries.* Employers should review and evaluate salaries paid to women even though no formal complaint or charge has been filed. Conferences with the women economists involved may prove helpful in diagnosing situations in which women feel that their salary is inappropriate. Lower geographic mobility among women should not be assumed or used as a rationalization for lower salary. Employers should not base the pay of a new employee solely on the basis of previous pay. The federal government should not continue to base GS ratings for entering academic economists primarily on the basis of total salaries before entering government service. Rather, the GS rating should be based upon objective criteria relevant to the job description. Otherwise, discrimination against women economists entering government service will simply compound past discrimination resulting from denial of equal access to outside consulting and related activities.

(2) *Fringe Benefits.* Employers should review all fringe benefits for possible sex discrimination and ways to facilitate employment of women. Examples include health and life insurance, pensioning, tuition grants for

[10] In 1921 a woman graduate student at Stanford joined her professional association. When she married, she kept her membership; her husband was not then a member. Some years after that it seemed sensible for him to belong to the association and they made it a "family" membership, which they continued through 1972. In December they resigned their memberships. After some weeks the husband received a letter from the Secretary's office expressing regret for his resignation after having been a member for so many years and offering him a membership without publications. No such letter was sent to his wife although she had been a member for over half the century. (This information was presented to the Committee by Lucy Winsor Killough, a retired member of the Wellesley College faculty.)

[11] For many years, the Yale Economics Department conducted official business at a male-only club.

children, mortgage or other loans at low interest rates, subsidized housing, child care facilities on campus and at conferences, recreational facilities, and various sorts of leave. Women should not be discriminated against because of an actual or potential maternity leave. Men and women economists should be offered the same facilities and resources for research, including assistants, offices, and equipment.

Resolution Ie) There shall be no distinction between men and women as to what is considered to constitute full-time employment.

Both part-time and full-time positions should be described completely with respect to the obligations of the persons appointed. For example, many academic appointments consist of a combination of duties: teaching, consulting, advising students, departmental governance, recruiting, supervising personnel, conducting research, representing the department, and so on. If one or more of such activities is optional, performance in the optional activity should not carry any weight in determining promotion or compensation. Those duties that are a necessary part of the job should be clearly stated and a minimum time should be specified.

Some women may wish part-time appointments, particularly for the few years while their children are small. Others may wish full-time appointments. Preference of individuals should be considered. Institutions should not base their hiring policy on the myth that most working women are interested in part-time work primarily to earn pin-money. On the other hand, institutions should increase the part-time options for those, men or women, who are interested. (See Resolution III.)

Care must be taken that "part-time" is not another job title that is used as a convenient way to deny job opportunities for women who wish to work, or in fact do work full time.

Resolution If) Employment may not be refused to any qualified economist on the grounds of family relationship to another employee.

Decisions regarding appointment, promotion, salary, or tenure should be unaffected by the presence of a close relative in the same or related firm, department, or government agency. However, employees should neither initiate nor participate in institutional decisions involving a direct benefit (initial appointment, retention, promotion, salary, leave of absence, etc.) to members of their immediate families.

Much of the past discrimination against women has been related to their marital status as well as their sex.[12] Economists employed by a college or university, a firm, or a government agency with practices in conflict with those suggested here should campaign actively to have the rules or practices changed.

Without compromising standards in any way, special efforts should be made to facilitate the employment of couples who apply to institutions as teams. Such employment should be in keeping with the individual talents of the team members so that neither part will be specially burdened.

III. RESOLVED that the American Economic Association shall encourage flexibility in providing opportunities for education and employment on a part-time basis both for men and women.

Departments of economics should review all educational requirements that include a time specification. It is expected that a conscientious reexamination of existing procedures will lead to considerably more flexible

[12] "The invisibility of the female job candidate emerges nowhere more unselfconsciously than in the dossiers of young, married graduate students. The dossiers of undeniably brilliant, serious, promising women, filled with letters from eminent advisers, very frequently compare the woman with her husband, stereotype her as the teacher not the scholar-thinker, and so the less valuable member of the couple. Indeed, one often wonders for whom the letter was written. One woman's letter contains this sentence: 'Mrs. —'s husband — is an excellent scholar, rather more disciplined and professional . . . . Mrs. — complements him with her more imaginative and enthusiastic . . . literary rather than historical perspective.' . . . Or another begins: '— and her very able husband' and continues 'like her husband, she . . .' " Such letters affect the reader by reinforcing his notion that a woman is an appendage, her career second to her husband's; her talents shine in the light of his. [M.L.A. Newsletter, p. 3]

arrangements at many academic institutions.

The question of part-time employment is a matter of department or institutional policy, but the question of whether the policy applies equally to men and women is not. It is imperative that in considering whether to allow (or encourage) part-time appointments, only the impact on work activities be considered, and not the reasons why people wish part-time appointments. If policies on part-time appointments enable an employer to secure an expert who will teach one course or do one project although engaged elsewhere in other paid employment, then part-time employment should also be available to women—or men—engaged in work ordinarily considered a nonmarket transaction. The person who carries a portion of a conventional full-time load should have assigned duties and base compensation (full-time equivalent) comparable to those of full-time appointments, and duties, salaries and fringe benefits should be prorated. Academic departments should particularly look at such fringe benefits as research assistants and travel grants which tend to increase professional competence.

The part-time person who teaches one course or does one project may be hired on a consulting basis for a flat fee. In such cases no fringe benefits need be available if the fee is adjusted accordingly. Economists at academic institutions can encourage and assist nonacademic organizations to increase part-time opportunities even if department policy has ruled against this for faculty positions. Credentials, skills, and professional creativity required of part-time personnel should be at least equivalent to the levels required of full-time employees so as to justify the equivalent base pay. Part-time appointments should not be a way to get cheap, low quality service. Nor should they be used as means of psuedo-compliance with Affirmative Action Plans.

The Committee is willing to discuss any of the above guidelines in the context of particular situations or additional suggestions of ways to improve current employment conditions. Members of the American Economic Association should report to the Committee on the Status of Women in the Economics Profession any cases that appear to involve sex discrimination directed against women economists. Members are reminded that the Wage and Hour Division of the U.S. Department of Labor as a matter of course receives complaints of wage or salary discrimination on a confidential basis, with the possibilities of back pay being awarded. Furthermore, the Equal Employment Opportunity Commission acts on complaints of unequal advancement opportunities for women.

III. Summary of Action Responsibilities

To comply with the resolutions adopted by the American Economic Association on December 28, 1971, a summary of action responsibilities, italicized below, has been prepared. Their central thrust should command virtually unanimous support: to eliminate extraneous considerations such as an individual's sex from any judgment of ability, performance, or potential.

I. RESOLVED that the American Economic Association declares that economics is not exclusively a man's field. The Association herewith adopts a positive program to eliminate sex discrimination among economists, whether employed in universities and colleges, industry, finance, publishing, or other endeavors. The President shall make known, by all available means, the Association's adoption of the following principles:

a) To redress the present low representation of women in the economics profession, the Association shall actively encourage the study of economics by women at all levels of education.

ACTION RESPONSIBILITY: *It is our obligation to affirm, in precept and action, that there are no genetic distinctions between the sexes which would preclude the study of economics by women on a proportionately equal basis with men. Since the role prejudice on the part of role occupants and role demanders is an acquired (i.e., learned) characteristic, educational institutions, government, and private industry should help dispel the prevailing myth that the current division of labor in the*

economics profession reflects relevant biological or genetic differences between the sexes.

b) No academic institution or department shall discriminate against women in admission to studies in economics or in the form or amount of financial aid. Every economics department shall actively encourage qualified women graduate students without regard to age, marital or family status, and shall actively promote their subsequent employment.

ACTION RESPONSIBILITY: *With respect to admissions, financial aid and placement, the primary concern should be individual merit, i.e., an objective assessment of the candidate's ability, performance, and potential—irrespective of sex, marital, or family status. With respect to recruitment and encouragement in the program, academic institutions and departments should be mindful of the need to redress past inequities and derelictions which have produced the present imbalance between the sexes in the economics profession. They should also be mindful of the positive contribution and enrichment of the educational process to be achieved through an increased participation of women. The profession can only stand to gain from the benefits of pluralist diversity and the recruitment of previously excluded, underutilized or unutilized talent.*

c) No employer, academic or otherwise, may discriminate against qualified women economists as candidates for positions, or for promotion or tenure, or for assignment of duties and responsibilities.

d) Salaries, fringe benefits, and facilities and resources for research for women shall be the same as those for men in the same position and rank.

e) There shall be no distinction between men and women as to what is considered to constitute full-time employment.

f) Employment may not be refused to any qualified economist on the grounds of family relationship to another employee.

ACTION RESPONSIBILITY: *In making appointment, retention, promotion, and tenure decisions, as well as in matters of compensation, fringe benefits, and prerequisites, women candidates shall be judged on their professional merit. The only relevant criteria shall be ability, potential, and performance. Care shall be exercised to avoid subtle as well as blatant, institutional as well as personal, forms of discrimination, especially where apparently innocuous regulations or policies impose differential burdens on women candidates. Institutional nepotism rules constitute the perhaps clearest departure from our central rule of judging candidates on their individual merit.*

II. RESOLVED that the American Economic Association establish a Committee on the Status of Women in the Economics Profession, numbering at least eight persons to be appointed by the President for a term of three years. The Association shall provide or seek funds for this Committee to investigate the extent of conformity to the principles stated above, and shall make recommendations for affirmative action. The Committee shall present an interim report at the next annual meeting. Its general findings, conclusions, and recommendations shall be published by the American Economic Association upon the Committee's request. When the Committee finds evidence of discrimination against women, it shall make this available for publication by the American Economic Association, and for the Association to present, as *amicus curiae*, in any complaint, remedial action, or suit.

ACTION RESPONSIBILITY: *Economists in educational institutions, government, and the private sector should help disseminate the findings of this Committee and its recommendations. The Committee wishes to assist in affirmative action programs and/or positive efforts to overcome role prejudice, but it also stands ready to receive complaints of discrimination. Rules to ensure proper procedures in handling such complaints are currently being formulated.*

III. RESOLVED that the American Economic Association shall encourage flexibility in providing opportunities for education and employment on a part-time basis for both men and women.

ACTION RESPONSIBILITY: *Making increasing provisions for education and employment on a part-time basis should be viewed as a technique for increasing individual opportunity and institutional flexibility. Such arrangements should not be allowed to serve as a cloak for evading compliance with affirmative action programs or for segregating women into underpaid and underprivileged professional categories.*

IV. RESOLVED that the American Economic Association appoint women economists as members of the editorial boards of its economic journals, that it actively encourage the appointment of women as program chairmen and participants at all future economic meetings, and that it urge companion associations to follow its example.

ACTION RESPONSIBILITY: *The Committee has written to the officers of regional and local economic associations as well as of allied social science associations, and to the editors of journals dealing with economics and economic affairs, urging that women economists be among those considered in selecting reviewers, referees, editorial board members, speakers, program arrangers, and so on. Those responsible for planning programs, conferences, commissioned articles or reports, and other opportunities for demonstrating professional achievement must remember that when women economists are less visible than men their competence or availability cannot be evaluated. The Committee has provided assistance in locating women economists and expects to continue to do so.*

IV. Conclusion

The recommended actions are only symbolic of needed changes in policy and attitude, if we are to correct the bizarre and irrational underrepresentation of women in the economics profession. The unemployment and underemployment of currently available talent, as well as the loss of potential talent, require positive, broad-gauged action to correct some structural imperfections in the professional labor market. To help eliminate these imperfections, one minimum step is continuing analytical study of the problem and regular, detailed reports to the Association and its members. In most instances—given the massive good will of our colleagues—the dissemination of information in itself will suffice to assure corrective action because, as Louis D. Brandeis once observed, "sunshine is the best disinfectant and electric light the most efficient policeman."[2] In other instances, to be sure, additional steps will be required to eliminate existing market imperfections and anomalies. This implies a continuing obligation of the Association and its members to consider alternative mechanisms, consistent with professional standards and ethics, to promote genuine equality of opportunity and meaningfully free access for all scholars and practitioners in the discipline of economics.

Committee Members

Carolyn Shaw Bell, Chair, Wellesley College
Martha O. Blaxall, Secretary, National Academy of Sciences
Walter Adams, Michigan State University
Francine Blau, Trinity College
Kenneth Boulding, University of Colorado
John Kenneth Galbraith, Harvard University
Collette Moser, Michigan State University
Barbara Reagan, Southern Methodist University
Myra Strober, Stanford University

NOTES

Members with suggestions for the meetings in San Francisco, December 28–30, 1974, are invited to send them to Rendigs Fels, Secretary-Treasurer, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212. The Secretary-Treasurer will review the suggestions and forward them to the Program Chairman. Papers at sessions sponsored by the American Economic Association are ordinarily invited rather than contributed. To be considered, proposals for this Association must be received by the Secretary-Treasurer no later than February 1, 1974. Economists wishing to give papers on econometrics or economic theory may want to submit them to the Econometric Society, which meets with the Association and annually schedules a number of contributed papers.

The Executive Committee of the American Economic Association at its meeting on March 2, 1973 voted to increase dues 5 percent effective January 1, 1974, subject to reconsideration at its meeting December 27, 1973. This action was taken under the provision of the bylaws permitting the Executive Committee to increase dues proportionate to increases in relevant costs and prices.

American scholars scheduled to participate in international meetings abroad may, as in the past, receive a travel grant from the American Council of Learned Societies. Under the new procedures adopted by ACLS effective October 1973, the applicant must obtain a standard application form from the appropriate society and return the completed form to the society by the applicable deadline: February 15 (for meetings scheduled June to September), June 15 (for meetings scheduled October to January), or October 15 (for meetings scheduled February to May). Applicants will be carefully screened by the society. ACLS instructions state: "Awards are restricted to humanists and to those social scientists and legal scholars who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings concerned with the humanistic aspects of their disciplines." Inquiries should be addressed to Rendigs Fels, Secretary-Treasurer, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

Calls for Student Papers

The Conference on Research in Income and Wealth will include a student papers session in its meeting at the University of Michigan, May 15, 16, and 17, 1974. The focus of the meeting will be the distribution of income and wealth, broadly defined to include job perquisites and social benefits. A maximum of three papers by students will be selected for presentation and a discussant will be appointed for participation in the session. Any person currently working toward a degree at any level may offer a paper for consideration. The papers should be unpublished, no more than 30 pages, and not currently under consideration by a publisher. Interested students should send papers to the Conference Chairman, Dr. F. Thomas Juster, Survey Research Center, Institute for Social Research, University of Michigan, Ann Arbor, Michigan 48106, by Feb 1, 1974.

Omicron Delta Epsilon is cosponsoring with Tax Analysts and Advocates a new annual essay contest on federal taxation named in honor of Paul H. Douglas, who has gained recognition both as a leading proponent of tax reform and as a distinguished public finance economist. The ODE-TAA annual contest is for the best undergraduate or graduate student essay of up to 5,000 words on any topic relevant to the U.S. federal tax system. The winning paper will be published in the Omicron Delta Epsilon journal, *The American Economist* and a cash award of $250 will be made. Two $100 awards will be made as second prize. Selection of winners will be made by Oct. 1, 1974. Essays should be sent to Tax Analysts and Advocates, 732 17th Street, Washington, D.C. 20006, by June 1, 1974.

The Southern Regional Science Association (*SRSA*) announces an award program for the best study submitted by undergraduate or graduate students, or those who have completed degree requirements in the academic year 1973–74. The author of the best study on a subject within the scope of regional science will receive an honorarium of $100 and be invited to present his or her paper at the annual *SRSA* meeting in Washington, D.C., April 4–5, 1974. All studies must be no longer than 15 typewritten pages, double spaced three copies submitted in edited form with footnotes at the end of the text. The name of the author his or her affiliation, and the title of the study should be on a separate cover sheet. The first text page should contain only the title and text. The cover page will be removed before the study is reviewed. All studies must be postmarked no later than Feb. 1, 1974 and sent to the Chairman of the *SRSA* Competition Committee: James M. Stepp, Department of Agricultural Economics, Clemson University, Clemson, South Carolina 29631.

The Journal of Law and Economics is in the process of collecting and cataloging the private papers of the late Henry C. Simons. They are seeking contributions to their collection in the form of manuscripts written by Simons and recollections or biographical materials by his associates and students as well as information concerning the location and contents of any other collections of Simons' papers. When completed, the collection will be available to scholars at the University of Chicago Law Library. Please send any contributions to R. H. Coase, *Journal of Law and Economics*, University of Chicago Law School, 1111 East 60th Street, Chicago, Illinois 60637.

The Office of Naval Research and the George Washington University, with the cooperation of the Air Force Office of Scientific Research and the Army Research Office, announce a Logistics Research Conference to be held at the George Washington University, Washington, D.C., May 8–10, 1974. Contributed papers are welcome. Abstracts and inquiries may be addressed to Ms. Henrietta Jones, Department of Operations Research, The George Washington University, Washington, D.C. 20006. Telephone 202+ 676-7504.

The Joint Committee on Eastern Europe of the American Council of Learned Societies and the Social Science Research Council wishes to draw attention to three of its grant programs: grants for postdoctoral research to a maximum of $3500; grants for study of East European languages to a maximum of $1000; grants ranging between $2000 and $5000 for the support of conferences. For details of eligibility and information which must be supplied in requesting application forms, write to Office of Fellowships and Grants, American Council of Learned Societies, 345 East 46 Street, New York, New York 10017.

The National Tax Association announces the 1973 award winners in the annual competition for outstanding doctoral dissertations in government finance and taxation. The $1,500 first prize award was won by John H. Bowman of Ohio State University (now at the Advisory Commission on Intergovernmental Relations), with his entry, "Cost and Benefit Spillouts as Factors Affecting Local Taxation for Public Schools." Honorable mention awards of $500 each were won by A. Mitchell Polinsky of Massachusetts Institute of Technology, (now at Harvard University), "Essays in Public Sector Economics: Central and Local" and Roger W. Schmenner of Yale University "City Taxes and Industry Location." The members of the 1973 Selection Committee were Professors Harvey E. Brazer, Arthur D. Lynn, Oliver Oldman, and James A. Papke. Information on the 1974 award competition may be obtained from Professor James A. Papke, Department of Economics, Krannert Graduate School of Industrial Administration, Purdue University, West Lafayette, Indiana 47906.

The Fourth World Congress of the International Economic Association will be held from August 19 to 24, 1974 in Budapest, Hungary, on the theme "Economic Integration: Worldwide, Regional, Sectoral." The program committee of 12 economists under the chairmanship of Fritz Machlup has invited 66 persons from 37 countries to fill places on the program. It provides for 12 main papers, 27 discussion papers, 10 opening statements for the discussions in separate working groups, 10 reports from chairmen of the working groups, and 7 chairmanships of plenary sessions. Many more, indeed several hundreds of those attending the Congress, will have an opportunity to participate in the discussions in the working groups, which will meet simultaneously in 5 half-day sessions.

The topics assigned to the working groups and their chairmen are: Measuring the Degree or Progress of Economic Integration (Eric Lundberg, Sweden); Sectoral Integration: Agriculture, Transport, Energy, Selected Industries (Joszef Pajestka, Poland); Industrial Policy: Location, Technology, Multinational Firms, Competition, and Integration of Product Markets (Harry G. Johnson, U.K.); Migration and Integration of Labor Markets (Orlando d'Alauro, Italy); International Capital Movements and Integration of Capital Markets (Herbert Giersch, Western Germany); Monetary and Fiscal Integration (Raymond Barre, France); Socio-Political and Institutional Aspects of Integration (Shigeto Tsuru, Japan); Integration of Less Developed Areas and of Areas on Different Levels of Development (I. G. Patel, India); Integration by Market Forces and through Planning (Bela Czikos-Nagy, Hungary); World Trade and Intraregional Trade: Trends and Structural Changes (P. J. Verdoorn, Netherlands). The following economists from the United States will present main papers, discussion papers, or opening statements: Bela Balassa, Richard N. Cooper, Gottfried Haberler, Peter Kenen, and Marina v. N. Whitman. The complete program will be published in the March 1974 issue of this *Review*.

Attendance is open to all members of the American Economic Association and of other national associations belonging to the I.E.A. The Hungarian arrangements committee has reserved over 2000 beds in Budapest. It is hoped that several hundred economists from the United States will attend. Registration fee at the Congress will be $50—reduced to $30 for early reservation up to March 31, and $40 from April 1 to July 31. Fees for students are one-half, and fees for members of the family accompanying a participant are $5 each. Forms for registration will be distributed through universities, research organizations, the secretariat of the AEA, and by direct mail from the Hungarian Economic Association, 1370 Budapest, Pf. 544, Hungary.

The International Economic Association will hold a workshop on "Population and Development," in cooperation with Bosphorus University, Istanbul, from September 2 to 14, 1974. The workshop will consider interrelations between economic and demographic factors in development. Attendance will be limited to 25 economists with experience in development programs. They need not have prior specialized experience in the subject of population. Expert discussion leaders will provide guidance. Preference will be given to senior and other responsible officials of government but academic economists will also be considered. All proceedings will be in English.

Persons wishing to be considered for invitation may apply by letter to the organizing committee. Please describe your relationship to development administration and policy, and include a curriculum vitae. Fluency in English is required. Participants attending the entire workshop will receive transportation, maintenance, and a modest per diem. Write to Dr. Paul Demeny, Director, The Population Council, 245 Park Avenue, New York, New York 10017, U.S.A. Other committee members are Professor Emre Gonensay and Dr. Frederic C. Shorter. Inquiries will be accepted up to March 15, and invitations will be extended by April 15, 1974.

The number of confirmed appointments through the National Registry for Economics, which was established in 1966, exceeds 1,200. Mrs. Theresa R. Scholl has been its manager since its inception. The National Registry is part of the nationwide professional placement network of the U.S. Employment Service, which is now celebrating its fortieth anniversary. For further details, see the section below on Employment Services.

Papers are solicited for the sixth Amos Tuck School Seminar on Problems of Regulation and Public Utilities, sponsored by the American Telephone and Telegraph Company, to be held in late August 1974 at Dartmouth College. The seminar will be attended by 30 conferees chosen from academic institutions throughout the country. It consists of 7 or 8 sessions over a 4-day period. The sessions provide a forum for the presentation and discussion of new ideas and innovative work in analyzing regulated firms, regulatory processes, and problems of public welfare.

We invite those with an interest in this area to suggest names of possible speakers or to apply themselves. The aim of the seminar is to introduce the research both of young scholars beginning their careers and of scholars who have only recently turned their attention to public utility problems. Therefore, suggestions of speakers must be limited to scholars in these categories. Those chosen to present papers will receive support for research and writing, in addition to travel and living expenses at the seminar. Please send suggestions to the coordinator of the seminar before February 23, 1974. Include two copies of each of the following: biographical information; samples of written work; and a proposal to be developed for presentation.

This is not a request for conferee applications. Application forms and further information will be mailed to institutions in March 1974. The director of the seminar is Professor Duncan M. Holthausen, Jr. Please direct all suggestions and correspondence to: Coordinator, Seminar on Problems of Regulation and Public Utilities, The Amos Tuck School of Business Administration, Dartmouth College, Hanover, New Hampshire 03755.

Deaths

Richard C. Bernhard, professor of economics, University of Utah, June 19, 1973.

David M. Harrison, professor emeritus, Ohio State University, June 17, 1973.

John W. Leonard, professor of economics and dean of School of Business, Southern Illinois University, Mar. 18, 1973.

Karl Pribram, professor emeritus, Frankfurt University; economist, retired, U.S. government; Washington, D.C., July 14, 1973.

Retirements

Claude A. Campbell, professor emeritus of finance, Florida State University, June 1973.

Troy J. Cauley, professor of economics, Indiana University, June 15, 1973.

J. Herschel Coffee, department of economics, West Texas State University, Aug. 31, 1973.

George E. Hunsberger, department of economics, College of Business Administration, University of Arkansas, June 30, 1973.

Janis Labsvirs, Indiana State University, professor of economics, June 30, 1973.

Charles N. Lanier, professor of economics and business administration, University of Delaware, Sept. 1973.

Herman E. Michl, professor of economics and business administration, University of Delaware, Sept. 1973.

Frances Simmons, Western Kentucky University, June 1973.

Philip E. Taylor, professor and former head, department of economics, University of Connecticut, Sept. 1973.

Visiting Foreign Scholars

Geoffrey P. Braae, University of Auckland: visiting professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1973.

Yakar Kannai, Hebrew University, Jerusalem: visiting professor, department of mathematics, Center for Mathematical Studies in Economics and Management Science, Northwestern University, Sept. 1973-June 1974.

Edi Karni, Tel Aviv University: visiting assistant professor, Ohio State University, summer quarter 1973.

John R. Moroney, Tulane University: visiting professor, department of economics and commerce, Simon Fraser University, May 1, 1974.

Aba Schwartz, Tel Aviv University: visiting associate professor, Ohio State University, autumn quarter 1973.

Turgut Var, University of Kansas: visiting associate professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1973.

Promotions

Robert F. Adams: professor of economics, University of California, Santa Cruz, July 1, 1973.

Theodore E. Allison: assistant secretary, Office of the Secretary, Board of Governors of the Federal Reserve System, June 10, 1973.

B. Wylie Anderson: associate professor of economics, University of Northern Iowa, Sept. 1973.

Ahmed N. A. Azim: associate professor, faculty of business, University of Calgary, July 1, 1973.

Forrest C. Blodgett: associate professor of economics, Linfield College.

Edward G. Boehne: senior vice president, Federal Reserve Bank of Philadelphia, Mar. 1, 1973.

James M. Boughton: associate professor of economics, Indiana University, July 1, 1973.

Paul L. Burgess: associate professor, Bureau of Business and Economic Research, Arizona State University, Sept. 1973.

Kenneth T. Cann: professor, department of economics, Western Kentucky University, Aug. 1973.

Charles Cathcart: assistant professor of economics, Pennsylvania State University, July 1, 1973.

Venkareddy Chennareddy: senior economist, Economic Research and Planning, Southern Research Institute.

Whewon Cho: professor of economics, Tennessee Technological University.

Ronald W. Chorba: associate professor, faculty of business, University of Calgary, July 1, 1973.

Caroline Clotfelter: assistant professor of economics, Mercer University, Sept. 1973.

Richard G. Davis: vice president, Research and Statistics Function, Federal Reserve Bank of New York.

Donn A. Derr: associate professor, Rutgers University, July 1, 1973.

Barry L. Duman: associate professor of economics, West Texas State University, Sept. 1, 1973.

Irwin Feller: professor of economics, Pennsylvania State University, July 1, 1973.

Ismail A. Ghazalah: associate professor, department of economics, Ohio University, Sept. 1, 1973.

W. Lee Hoskins: vice president-research, Federal Reserve Bank of Philadelphia, Mar. 1, 1973.

Katherine Hsiao: professor of economics, Indiana State University, Aug. 23, 1973.

David N. Hyman: associate professor of economics, North Carolina State University, July 1, 1973.

John E. Ikerd: extension associate professor of economics, North Carolina State University, July 1, 1973.

Ira P. Kaminow: economic adviser, Federal Reserve Bank of Philadelphia, Mar. 1, 1973.

Jerry L. Kingston: associate professor, Bureau of Business and Economic Research, Arizona State University, Sept. 1973.

Michael A. Klein: associate professor of economics, Indiana University, July 1, 1973.

V. N. Krishnan: associate professor, department of economics, Bowling Green State University, Sept. 1, 1973.

Robert J. Lawrence: associate adviser, Division of Research and Statistics, Board of Governors of the Federal Reserve System, June 10, 1973.

Robert L. Lawson: professor of economics, Ball State University, Sept. 1973.

Wayne A. Long: associate professor, faculty of business, University of Calgary, July 1, 1973.

James B. McDonald: associate professor of economics, Brigham Young University, Sept. 1973.

Charles E. McLure, Jr.: professor in economics and finance, Rice University, July 1973.

Paul Meek: monetary adviser, Open Market Operations and Treasury Issues Function, Federal Reserve Bank of New York.

Jacob B. Michaelsen: professor of economics, University of California, Santa Cruz, July 1, 1973.

Donald J. Mullineaux: senior economist, Federal Reserve Bank of Philadelphia, Mar. 1, 1973.

John A. Naylor: associate professor, department of economics, College of Wooster, Sept. 1, 1973.

Jon P. Nelson: associate professor of economics, Pennsylvania State University, July 1, 1973.

E. C. Pasour, Jr.: professor of economics, North Carolina State University, July 1, 1973.

Nicholas S. Perna: chief, Business Conditions Division, Federal Reserve Bank of New York.

A. Marshall Puckett: vice president, Accounting Control Function, Federal Reserve Bank of New York.

John H. Riew: professor of economics, Pennsylvania State University, July 1, 1973.

Richard L. Ruth: professor of economics, Northeastern Illinois University, July 1, 1973.

Gerald W. Sazama: associate professor of economics, University of Connecticut, Oct. 1973.

Vishwa S. Shukla: associate professor, department of economics, Ohio University, Sept. 1, 1973.

Nancy D. Sidhu: associate professor of economics, Northeastern Illinois University, Sept. 1973.

James D. Smith: professor of economics, Pennsylvania State University, July 1, 1973.

Ronald Soligo: professor of economics, Rice University, July 1973.

W. E. Spellman: associate professor of economics, Coe College, Sept. 1, 1973.

Gary H. Stern: manager, domestic research department, Federal Reserve Bank of New York.

Edmund G. Sugars: professor, faculty of business, University of Calgary, July 1, 1973.

Rudolf Thunberg: assistant vice president, Research and Statistics Function, Federal Reserve Bank of New York.

George M. von Furstenberg: professor of economics, Indiana University, July 1, 1973.

Howard M. Wachtel: associate professor, department of economics, American University, Sept. 1, 1973.

Ronald D. Watson: senior economist, Federal Reserve Bank of Philadelphia, Mar. 1, 1973.

William W. Wiles: assistant director, Division of Supervision and Regulation, Board of Governors of the Federal Reserve System, June 10, 1973.

James E. Zinser: associate professor of economics, Oberlin College.

Administrative Appointments

B. Wylie Anderson: head, department of economics, University of Northern Iowa, Sept. 1973.

Earl Baggerly: dean, Night School, Mercer University, July 1973.

Peter S. Barth, U.S. Department of Labor: head, department of economics, University of Connecticut, Sept. 1, 1973.

Raymond R. Beneke: chairman, department of economics, Iowa State University, Apr. 16, 1973.

Eric Brucker: chairman, department of economics, University of Delaware, Sept. 1973.

Sherrill Cleland, Kalamazoo College: president, Marietta College and professor of economics, July 1, 1973.

Robert F. Cook: chairman, department of economics, Indiana State University, Aug. 23, 1973.

Ervin J. Doak: chairman, department of economics, Saint Mary's University, Halifax, July 1, 1973.

Barry L. Duman: head, department of economics, West Texas State University, Sept. 1, 1973.

John W. Hannaford: associate dean, College of Business, Ball State University, Sept. 1972.

Robert T. Holland: co-chairman, Graduate Division, and co-chairman, Division of Business Administration, Woodbury College, May 1972.

Robert R. Jost: chairman, department of economics, Ball State University, Sept. 1972.

James A. Kane, University of Massachusetts: assistant secretary of Manpower Affairs, Commonwealth of Massachusetts, May 1973.

Richard D. Karfunkle, Laird, Bissell & Meeds, Inc.: vice president and chief economist, Abraham & Co., Inc., Delaware.

Hirschel Kasper: chairman, department of economics, Oberlin College.

Pauline W. Kopecky: director, University Affirmative Action Program, Oklahoma State University, Aug. 15, 1973.

Jacob B. Michaelsen: chairman, Board of Studies in Economics, University of California, Santa Cruz, July 1973.

Edward H. Murphy: assistant to the dean, faculty of Business, University of Calgary, 1973–74.

John C. Narver: chairman, department of marketing, transportation, and international business, University of Washington, Sept. 1974.

Leo J. Navin: chairman, department of economics, Bowling Green State University, Sept. 1973.

Stephen G. Peitchinis: dean, faculty of business, University of Calgary, Apr. 1, 1973.

Richard L. Ruth, Saint Mary's University, Halifax: chairman department of economics, Northeastern Illinois University, July 1, 1973.

James Satterfield: director of Admissions, Mercer University, spring 1973.

A. Ross Shepherd, assistant provost, University of Missouri-Kansas City, June 1, 1973.

David J. Smyth: chairman, department of economics, Claremont Graduate School, July 1, 1973.

Gary C. Taylor, National Water Commission: assistant deputy administrator, Economic Research Service, USDA, July 1973.

Walter J. Wadycki: assistant vice chancellor for academic affairs, University of Illinois at Chicago Circle, Aug. 16, 1973.

Frank E. Wagner: chairman, department of economics, University of Missouri-Kansas City, June 1, 1973.

James H. Weaver: chairman, department of economics, American University, Sept. 1, 1973.

Elmus R. Wicker: chairman, department of economics, Indiana University, July 1, 1973.

Robert Willard: chairman, Division of Business and Economics, Mercer University, July 1973.

New Appointments

Fred J. Abraham: assistant professor of economics, University of Northern Iowa, Sept. 1973.

Adebayo Akerele: lecturer, department of economics, Rutgers-The State University, July 1973.

Robert J. Anderson: associate professor of economics, director, Center for Study of Environmental Policy, Pennsylvania State University, July 1, 1973.

V. Balachandran, Carnegie-Mellon University: associate professor of decision sciences, department of managerial economics and decision sciences, Northwestern University, Sept. 1973.

M. Alan Baughcum: instructor of economics, North Carolina State University, Aug. 1973.

David C. Beek: economist, Balance of Payments Division, Federal Reserve Bank of New York.

Thomas E. Borcherding, Virginia Polytechnic Institute and State University: associate professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1973.

Leigh B. Boske, Stockton State College: senior economist, Wisconsin Department of Transportation, May 1973.

William W. Brooks: instructor of economics, North Carolina State University, Aug. 1973.

Leonard R. Burgess: visiting professor of management, Temple University, Sept. 1973.

Richard Butler, Massachusetts Institute of Technol-

ogy: assistant professor of economics, Rice University, July 1, 1973.

C. Stuart Callison, Cornell University: assistant professor of economics, Ohio University, Sept. 1, 1973.

Geoffrey Carliner, University of Wisconsin, Madison: assistant professor, department of economics, Oberlin College, Sept. 1973.

Pao Lun Cheng, University of Massachusetts: professor, department of economics and commerce, Simon Fraser University, Jan. 1, 1974.

Peter K. Clark: visiting research fellow, National Bureau of Economic Research, 1973–74.

Benjamin I. Cohen: research associate, National Bureau of Economic Research, July 1, 1973.

A. Edward Day: assistant professor of economics, University of Nebraska-Lincoln, Sept. 1973.

Paul DeRosa: economist, Money and Finance Division, Federal Reserve Bank of New York.

James E. Easley, Jr.: instructor of economics, North Carolina State University, Sept. 1973.

Michael G. Ellis: assistant professor, department of economics, New Mexico State University, Aug. 1973.

Thomas J. Espenshade, Bowdoin College: assistant professor of economics and research associate of Population and Manpower Research Center, Florida State University, Sept. 1973.

Mary L. Eysenbach, University of Washington: assistant professor of economics, University of Utah.

Douglas Fisher: visiting professor of economics, Claremont Graduate School, Sept. 1973.

David T. Geithman: associate professor of economics, Russell Sage College, Sept. 1, 1973.

Philip M. Ginsberg: assistant professor, department of economics, Rutgers-The State University, July 1973.

Gerald Glyde: assistant professor of economics, Pennsylvania State University, Sept. 1, 1973.

Clive W. J. Granger, University of Nottingham, England: professor of economics, University of California, San Diego, July 1, 1973.

Michael J. Greenwood: associate professor, Bureau of Business and Economic Research, Arizona State University, June 1973.

Theodore Groves, University of Wisconsin: associate professor of managerial economics, department of managerial economics and decision sciences, Northwestern University, Sept. 1973.

Daniel S. Hamermesh, Princeton University: associate professor, department of economics, Michigan Stata University, Sept. 1973.

Stephen K. Happel: instructor of economics, North Carolina State University, Aug. 1973.

Kurt Hausafus, University of Illinois, Chicago Circle: assistant professor, department of economics, Oberlin College, Sept. 1973.

Dennis R. Heffley: assistant professor of economics, University of Connecticut, Sept. 1, 1973.

Anthony F. Herbst: associate professor, faculty of business, University of Calgary, July 1, 1973.

Dana C. Hewins, University of Illinois: assistant professor of economics, Ohio University, Sept. 1, 1973.

Mary C. Hilliard: instructor of economics, North Carolina State University, Aug. 1973.

Mary T. Holcomb: instructor of economics, North Carolina State University, Aug. 1973.

L. Dwight Israelsen, Massachusetts Institute of Technology: assistant professor of economics, Brigham Young University, Sept. 1973.

Suresh Jain, Yale University: assistant professor of decision sciences, department of managerial economics and decision sciences, Northwestern University, Sept. 1973.

William G. Johnson, Rutgers University: assistant professor of economics, Syracuse University, Sept. 1, 1973.

Sergei Kasakow: visiting assistant professor, Bureau of Business and Economic Research, Arizona State University, Sept. 1973.

Donald W. Katzner, University of Waterloo: lecturer in economics, University of California, San Diego, July 1, 1973.

Herbert M. Kaufman: assistant professor, Bureau of Business and Economic Research, Arizona State University, Sept. 1973.

Christopher King: instructor of economics, University of Utah.

Jack L. Knetsch: professor, department of economics and commerce, Simon Fraser University, May 1, 1974.

Conway L. Lackman: assistant professor, department of economics, Rutgers-The State University, July 1973.

John Landon, Case-Western University: associate professor of economics, University of Delaware, Sept. 1973.

Stephen B. Levinson: instructor, department of economics, Rutgers-The State University, July 1973.

Kenneth Lewis, Boston College: associate professor of economics, University of Delaware, Sept. 1973.

Stephen E. Lile: associate professor of economics, Western Kentucky University, Aug. 1973.

Cliff Lloyd, University of Iowa: professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1973.

Donald C. MacCharles: department of economics, McMaster University, July 1973.

William A. McEachern: assistant professor of economics, University of Connecticut, Sept. 1, 1973.

James A. McMahon, I.C.A.O., Montreal: industry economist, Board of International Affairs, Civil Aeronautics Board, Sept. 1973.

J. C. McManus, Carleton University: associate professor, department of economics, McMaster University, 1973–74.

W. Edward McMullan: assistant professor, faculty of business, University of Calgary, July 1, 1973.

Sherman J. Maisel: senior research staff, National Bureau of Economic Research, June 1, 1973.

Vincent J. Malanga, Fordham University: economist, Federal Reserve Bank of New York, Sept. 1, 1973.

John P. Matilla, Ohio State University: assistant

professor of economics, Iowa State University, Sept. 1, 1973.

Eileen Mauskopf: lecturer, department of economics, Rutgers-The State University, July 1973.

Robert H. Miles: instructor of economics, North Carolina State University, Aug. 1973.

Paul A. Montavon: economic advisor, U.S. Permanent Mission to the Organization of American States, July 23, 1973.

Francis Mulvey: assistant professor, department of economics, Bowling Green State University, Sept. 1973.

Dick K. Nanto, Harvard University: assistant professor of economics, Brigham Young University, Sept. 1973.

Philip Nelson: research associate, National Bureau of Economic Research, July 1, 1973.

Norman P. Obst, University of Washington: assistant professor, department of economics, Michigan State University, Sept. 1973.

Robert T. Owen: assistant professor, faculty of business, University of Calgary, July 1, 1973.

Avinoam Perry, Indiana University: assistant professor of decision sciences, department of managerial economics and decision sciences, Northwestern University, June 1973.

James R. Prescott, Temple University: professor of economics, Iowa State University, Sept. 1, 1973.

David Puryear, Princeton University: assistant professor of economics, Syracuse University, Sept. 1, 1973.

Donald Ratajczak, University of California, Los Angeles: associate professor of economics and director, Georgia State University Economic Forecasting Project, Georgia State University, July 1, 1973.

Roger Riefler: associate professor of economics, University of Nebraska-Lincoln, Sept. 1973.

R. Lynn Rittenoure, University of Texas-Austin: assistant professor of economics and operations research, Navy Management Systems Center, Naval Postgraduate School, Sept. 1, 1973.

Roy Rotheim: assistant professor, department of economics, Bowling Green State University, Sept. 1973.

R. Robert Russell, University of California, Santa Barbara: associate professor of economics, University of California, San Diego, 1972–73.

Daniel H. Saks: visiting research fellow, National Bureau of Economic Research, 1973–74.

Bertram Schoner, University of Iowa: professor, department of economics and commerce, Simon Fraser University, May 1, 1973.

Robert A. Schultz: associate professor, faculty of business, University of Calgary, July 1, 1973.

Suresh P. Sethi, Rice University: visiting assistant professor, faculty of management studies, University of Toronto, July 1973.

Berndt A. Sigloch: instructor, department of economics and commerce, Simon Graser University, Sept. 1, 1973.

Irwin H. Silberman, New York University: associate professor, Queens College, City University of New York, 1973–74.

Ron Stanfield: assistant research environmental economist, Center for Marine Affairs, Scripps Institution of Oceanography, Aug. 1, 1973.

Wayne Stevenson, Middlebury College: assistant professor of economics, University of Utah.

Edward Stohr, University of California, Berkeley: assistant professor of decision sciences, department of managerial economics and decision sciences, Northwestern University, Sept. 1973.

Arie Tamir, Case-Western Reserve University: visiting assistant professor of decision sciences, department of managerial and decision sciences, Northwestern University, Sept. 1973.

Marie C. Thursby: visiting assistant professor of economics, North Carolina State University, Aug. 1973.

William P. Travis: professor of economics, Indiana University, Jan. 1974.

William H. Wallace: professor of economics and assistant department head for management, North Carolina State University, July 1973.

Yoram Weiss: research associate, National Bureau of Economic Research, Sept. 1, 1973.

J. D. Welland: department of economics, McMaster University, Jan. 1, 1974.

Roy E. Welsch: senior research associate, National Bureau of Economic Research, Computer Research Center, June 1, 1973.

John Wenninger: economist, Market Statistics Division, Federal Reserve Bank of New York.

Michael R. Wickens: adjunct associate professor, department of economics, Rutgers-The State University, July 1973.

W. Philip Windham: special lecturer of economics, North Carolina State University, Aug. 1973.

Christine Wollan: economist, European department, International Monetary Fund, May 1973.

Jong Keun You: lecturer, department of economics, Rutgers-The State University, July 1973.

Leaves for Special Appointments

Ghassan M. Arnaoot, West Texas State University: International Monetary Fund, Aug. 1, 1973.

Robert E. Berney, Washington State University: senior academic resident in public finance, Advisory Commission on Intergovernmental Relations, Aug. 1973.

Bernard H. Booms, Pennsylvania State University: economist in residence, City Manager's Office, Tacoma, Washington, July 1973–Aug. 1974.

James M. Boughton, Indiana University: administrator, Monetary Division, economics and statistics department, Organization for Economic Cooperation and Development, Sept. 1973.

Daniel W. Bromley, University of Wisconsin, Madison: economist, Office of the Secretary, U.S. Department of the Interior, Washington, D.C., Sept. 1973–Aug. 1974.

Leland S. Case, Brigham Young University: senior research economist, Association of American Railroads, Sept. 1973.

Edwin G. Charle, Ohio University: Fulbright Fellow, Cuttington College, Monrovia, Liberia, July 1, 1973.

Charles R. Chittle, Bowling Green State University: Institute for World Economics, Kiel University, Germany, June 1973–Aug. 1974.

Steven R. Cox, Arizona State University: Federal Trade Commission, July 1973.

Thomas F. Dernburg, Oberlin College: fiscal economist, International Monetary Fund, Feb. 1, 1973.

William G. Dewald, Ohio State University: special assistant for economic analysis and research, International Labor Bureau, U.S. Department of Labor, Washington, D.C., winter and spring quarters 1974.

Marvin R. Jackson, Arizona State University: Senior Fulbright-Hayes Program, Romania.

Roland H. Koller II, Brigham Young University: economist, Federal Trade Commission, July 1973.

Arlyn J. Larson, Arizona State University: State of Arizona, 1973–74.

Ben N. Matta, New Mexico State University: U.S. Department of Housing and Urban Development, Fort Worth, Texas, summer 1973.

Charles W. Meyer, Iowa State University: Long Range Research Branch, Social Security Administration, Washington, D.C., Sept. 1, 1973–Aug. 31, 1974.

John C. Narver, University of Washington: visiting professor, Norwegian College of Economics and Business Administration, Sept.–Dec. 1973.

James R. Ostas, Bowling Green State University: Federal Reserve Bank of Boston, June 1973–Aug. 1975.

Refugio I. Rochin, University of California, Davis: program assistant for rural development, The Ford Foundation, Bogota, Colombia, July 1, 1973–Sept. 1975.

Richard L. Schmalensee, University of California, San Diego: visiting assistant professor, Institute of Economics, Université Catholique de Louvain, Belgium, 1973–74.

David Segal, Oberlin College: visiting scholar, Resources for the Future, 1973–74.

S. W. Son, Slippery Rock State College: senior staff economist, Council of Economic Advisers, Washington, D.C. July 1973.

Dennis R. Starleaf, Iowa State University: visiting professor, economic section, Board of Governors of the Federal Reserve System, Washington, D.C., Sept. 1, 1973–Aug. 31, 1974.

Daniel B. Suits, University of California, Santa Cruz: visiting professor of economics, University of Hawaii, 1973–74.

P.A.V.B. Swamy, Ohio State University: consultant, Board of Governors of the Federal Reserve System, Washington, D.C., autumn quarter 1973.

George M. von Furstenberg, Indiana University: senior economist, Council of Economic Advisers, Washington, D.C., Sept. 1973.

Percy D. Warner III, University of Connecticut: Fulbright Fellow, Brazil, Sept. 1, 1973–July 31, 1974.

John C. Weicher, Ohio State University: U.S. Department of Housing and Urban Development, Washington, D.C.

Resignations

Terrell D. Blodgett, Southwest Texas State University, June 1973.

Eliyahu Borukhov, Ohio State University: Tel Aviv University, Sept. 1973.

J. Hayden Boyd, Ohio State University: Economics Division of Motor Vehicle Manufacturers Association, Sept. 1973.

Thomas F. Cargill, Purdue University: University of Nevada-Reno, Aug. 1973.

Richard J. Cebula, Ohio University: Emory University, June 30, 1973.

Ibrahim Eris, Rice University: University of São Paulo, July 1973.

Dieter Nowak, University of Calgary, June 30, 1973.

Philip D. Olson, University of Calgary, June 30, 1973.

David L. Paden, IU International Corporation: K. W. Tunnell Company, Inc., Aug. 1, 1973.

Charles E. Seagrave, Rice University: H.E.W., Washington, D.C., Dec. 1972.

Theodore L. Vaugh, Marietta College: Murray Fabrics, Inc, Kentucky, May 1, 1973.

NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment:

his new title (if any), his next place of employment (if known or if changed), and the date at which the change will occur.

C. Type each item on a separate 3x5 card, and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March,* November 1; *June,* February 1; *September,* May 1; *December,* August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review,* Box Q, Brown University, Providence, Rhode Island 02912.

SEVENTIETH LIST OF DOCTORAL DISSERTATIONS IN POLITICAL ECONOMY IN AMERICAN UNIVERSITIES AND COLLEGES

The present list specifies doctoral degrees conferred during the academic year terminating June 1973. Abstracts of many of the dissertations are supplied.

General Economics; including Economic Theory, History of Thought, Methodology, Economic History, and Economic Systems

EILEEN APPLEBAUM, Ph.D. Pennsylvania 1972. Toward a nonmarginalist approach to price formation and income distribution.

ELIZABETH E. BAILEY, Ph.D. Princeton 1972. Economic theory of regulatory constraint.

Part I presents a general framework that can accommodate many interesting models of regulatory constraint. Part II treats the most important interpretation of the general structure, namely, the Averch-Johnson model of rate-of-return regulation. Some ways of altering the model to include issues such as regulatory lag, peak-load pricing, and a rising cost of capital are also discussed. Wherever possible, the properties of the regulatory models are described both graphically and mathematically.

ROGER L. BECK, Ph.D. Chicago 1972. Patents, property rights, and social welfare: Search for a restricted optimum.

Several models are used to analyze the effect of structural features of the patent system on the system's objective: maximization of social profit on innovations. One implication is selected for testing—that social profit will be the most severely reduced by patenting of substitutes where profits on innovation are greatest. Data covering a period of several years in three industries are consistent with the hypothesis.

ALAN R. BECKENSTEIN, Ph.D. Michigan 1972. An optimization approach for evaluating multiplant scale economies.

ROBIN W. BOADWAY, Ph.D. Queen's 1973. Some aspects of the theory of externalities.

JOHN P. BONIN, Ph.D. Rochester 1973. Target specification, managerial rewards, and the socialist firm.

Optimal policies for a socialist firm are investigated in both static and dynamic models by considering the effects of various target and managerial reward specifications on quantity decisions. When targets are misspecified, the information generated from observing the firm's behavior is discussed. Misspecification involves targets which do not satisfy the firm's production function or input targets which are not cost minimizing for given factor prices. Finally, a preliminary investigation into intertemporal target variation is undertaken.

MARCEL BOYER, Ph.D. Carnegie-Mellon 1973. Essays in optimal growth theory: A dynamic programming approach.

JAMES B. BRADFIELD, Ph.D. Rochester 1973. A dynamic programming model of the stock market specialist.

Our specialist makes a market by announcing prices periodically throughout the trading day. He guarantees these prices by trading for his own account. His overnight inventory positions incur holding costs. The specialist maximizes the discounted expected value of his own net trading profits over a finite horizon of trading days. The optimal announced price depends on the time of day, the level of his inventory, and his exclusive knowledge of the "book" of limited-price orders.

DENNIS NAI-WEI CHAO, Ph.D. California (Santa Barbara) 1972. Consumer behavior, activity chains and socioeconomic model of family formation.

GEORGE SAW-HO CHUNG, Ph.D. Southern California 1973. Differential game theory approach to modeling dynamic imperfect market processes.

NINA W. CORNELL, Ph.D. Illinois (Urbana) 1972. The role of the nobility in agricultural change in Russia during the reign of Catherine II.

JAMES F. CROOK, Ph.D. Virginia Polytechnic Institute 1973. Separate vs. concurrent decision procedures for public goods provision under majority rule.

This study attempts to develop a theoretical rationale for the choice between separate and concurrent decision procedures by voting groups. Concurrent procedures involve simultaneous decisions on the outputs of many public goods while separate procedures determine outputs of public goods singly or in large subsets. General purpose legislatures are examples of the former and referenda or special purpose legislative boards are examples of the latter.

DAVID DAYAN, Ph.D. Princeton 1973. Vertical intergration and monopoly regulation.

This thesis deals with the motivation of the regulated firm to exercise vertical control, the effect of

vertical control on the firm's behavior, and, conversely, the impact of various regulatory policies on the behavior of the vertically integrated firm. Several models of the single stage and multistage firm under constraints are developed and analyzed using non-linear optimization techniques. The models are compared and assessed in terms of their implications for economic theory, practice, and public policy.

FLOYD R. DILL, Ph.D. Cornell 1973. The institutional possibilities and limitations of economic progress in antebellum Georgia: A social systems approach.

RICHARD C. EDWARDS, Ph.D. Harvard 1972. Alienation and inequality: Capitalist relations of production in bureaucratic enterprises.

This thesis investigates the internal structure of modern enterprises. Contradictions growing out of earlier systems of power have led capitalists to attempt to maintain control by embedding power relations in the organizational or technical structure of work. An empirical analysis based on data for 455 workers shows that the firm's incentives are significantly geared to control, and that firms highly reward control-related "noncognitive" worker characteristics. A final analysis (N=217) shows that similar noncognitive traits are importantly related to success in high school.

JOHN P. FARRELL, Ph.D. Wisconsin (Madison) 1973. Aspects of central banking in Poland, 1950–1970.

ANN N. P. FISHER, Ph.D. Connecticut 1973. Durable goods and consumer choice.

Demand decisions for ordinary continuously divisible commodities and durables are studied, where discrete durables may be purchased on installment plans. Via a two-stage process, the consumer is hypothesized to rank all affordable bundles of (dated) durables (with their payment plans), each matched with its optimal bundle of divisible goods. The effect on demand for ordinary goods resulting from price, income, or payment plan changes can be predicted only if the chosen durable bundle remains the same.

ARTHUR D. FRAAS, Ph.D. California (Berkeley) 1972. The impact of the policies of the second bank of the United Slates on the economy of the Ohio Valley: 1814–1829.

LEWIS FREIBERG, JR., Ph.D. Kentucky 1972. Political coalitions and the allocation of resources.

This dissertation builds an axiomatic model of direct democracy to examine the efficiency of the political allocation of resources. Pareto optimality, operationalized through Scitovsky's double compensation criteria, is used to examine the welfare effects of appending a bribery process to the model. Several theorems are then derived concerning the type, direction, size, and welfare effects of resulting bribes. With these theorems, one can predict the outcome and Pareto optimality of the resulting political allocation of resources.

GERARD O. GAUDET, Ph.D. Pennsylvania 1972. Imperfections in the market for capital goods: Their effects on optimal firm size and on the relative efficiency of monetary and fiscal policy.

DAVID E. R. GAY, Ph.D. Texas A&M 1973. Capital and the production process: A critical evaluation of the Böhm-Bawerk—Clark debate and its relation to current capital theory.

DONALD W. GREEN, Ph.D. California (Berkeley) 1972. Industrialization and the engineering ascendancy: A comparative study of American and Russian elites, 1870–1920.

SURINDER S. GUJRAL, Ph.D. Georgetown 1973. Population growth and issues in Indian economic history, 1851–1901.

The study provides a complete series on India's population, by provinces and states, and labor force estimates for the decades between 1851 and 1901. The analysis of the data questions the widely held contention that India experienced a rapid increase in population prior to 1872. The treatment of the period 1872 to 1921 as homogeneous with respect to population growth is questioned. The labor force estimates represent a marked departure from previous analysis of the census data on occupational distribution.

DOUGLAS R. HALE, Ph.D. Kansas 1972. Imperfect competition and general equilibrium.

This dissertation is concerned with establishing the existence of equilibrium for monopolistically competitive economies. Following Negishi, each monopolistic competitor is viewed as maximizing his profit relative to a perceived demand. The assumptions applying to individuals, competitive firms, and the resource endowment are explained. Sufficient conditions for the existence of equilibrium will further allow for nonincreasing, parametric external, and some cases of internal increasing returns to scale.

TOSHIHIKO HAYASHI, Ph.D. Stanford 1973. Theory of transaction and monetary equilibrium.

Building on a microeconomic analysis of the choice of optimal transactions as a relevant economic problem, this dissertation develops two general equilibrium models of monetary transaction economy. The main conclusion of the study is that it is the desirability of transactions as reflected in the non-Pareto efficiency of the initial allocation of commodities or in the "strong desirability" of transactions that guarantees a positive exchange value for fiat money in equilibrium.

THOMAS K. HOLMSTROM, Ph.D. Oklahoma State 1973. A theoretical analysis of Keynesian labor market assumptions and the macroeconomic adjustment process.

Keynes' labor market assumptions imply a positive

rather than a negative relationship between quantity demanded and the price level. The neo-Keynesian aggregate demand function which is obtained without reference to the labor market is a market equilibrium curve rather than an authentic demand curve. Three new equilibrium curves are presented which help to reveal aspects of the interdependence of the labor market and the other markets in the Keynesian system.

YASUHISA HOSOMATSU, Ph.D. Wayne State 1972. Static and dynamic analysis of Cournot type oligopoly models.

WALTER E. HUFF, Ph.D. Florida State 1972. Economics of the Yugoslav joint venture.

Yugoslavia is a socialistic country seeking ways to improve her economy; one of the more tradition shattering innovations she has introduced is the acceptance of foreign investment in joint ventures with Yugoslav enterprises. This major change in policy was taken in July 1967. Much to the surprise of many Yugoslavs, few investments were forthcoming. The purpose of this dissertation is to explain the initial failure of the Yugoslav Joint Venture Program to attract any substantial amount of foreign investment.

MING-JENG HWANG, Ph.D. Texas A&M 1973. Optimal sizes and shapes of market areas of firms.

This dissertation sets forth a theoretical as well as empirical model on market sizes and shapes, and investigates the sizes and shapes of market areas of firms in the United States. It is contended that small size market areas prevail in the United States. Moreover, it is observed that competitive firms would practice f.o.b. mill pricing in hexagonal shaped markets when market areas are small, and charge discriminatory prices when the areas are large.

EVAN JONES, Ph.D. Michigan State 1973 On the microeconomic theory of optimal capital accumulation.

This thesis explores certain implications of the dynamic neoclassical theory of factor demand; in particular, the problem of economics of scale. An attempt is made to extend the Marshallian concept of long-run average costs to a dynamic framework and to compare the modified equilibrium with those resulting from neoclassical theory. Further, Lerner's accepted interpretation of Keynesian investment theory is argued to suffer from a defect parallel to what in microeconomic theory is a false dichotomy between static and dynamic elements.

SERGEI S. KASAKOW JR., Ph.D. Washington State 1973. A study of managerial incentives in the Soviet Union.

This thesis examines the managerial incentive provisions of 1965 economic reforms for the *USSR*. They are reviewed in relation to Western literature on motivation for work and risk taking. State-chosen success indices (profits and sales) are considered for several firms and industries (Shchekino, Perm's, and Bol'shevichka). All major incentive experiments successfully achieved their planned objectives, but the new approaches were not widely extended, and plant management received minimal cooperation from supervising administrators.

J. THOM KELLY, Ph.D. Texas A&M 1972. A model of price search and allocation of time in the theory of consumer behavior.

A mathematical model is developed in which consumers can find lower commodity prices by investing time in search; prior contributions in price search theory are used in a formal demand-for leisure model. Specifically determined are effects on consumer behavior (leisure, work, and search), of changes in commodity prices, consumer wage rate, search efficiency and income.

MOHAMMED A. KHAN, Ph.D. Yale 1973. Large exchange economics.

MEIR G. KOHN, Ph.D. Massachusetts Institute of Technology 1973. Sequential decision making and the theory of the firm.

PANAYOTIS G. KORLIRAS, Ph.D. Rochester 1973. Essays in disequilibrium macrodynamics.

The theme of these essays is the development of a macroeconomic theory under the nontâtonnement assumption. After a critical review of the related literature, one nonmonetary model and one model of the financial sector are presented. The last essay, integrating both into a general model with variable employment, examines the nature of the adjustment processes and the stability of the short-run equilibrium.

ARTHUR J. KUHN, Ph.D. California (Berkeley) 1972. An application of a system control model to business history: The General Motors Corporation under Alfred P. Sloan, 1920 to 1935.

WAYNE H. LANCASTER, Ph.D. Claremont School 1973. A reconsideration of the Phillips curve for the United States.

JEROME K. LAURENT, Ph.D. Indiana 1973. The development of harbors, waterborn shipping, and commerce at six Wisconsin ports on Lake Michigan through 1910.

This study examines the circumstances which influenced the development of harbors, waterborne shipping, and commerce, at six major Wisconsin ports on Lake Michigan: Kenosha, Racine, Milwaukee, Sheboygan, Manitowoc, and Green Bay. Although initial developments at the several ports (except for Green Bay) took place in the period 1836–65, the era 1866–1910 is especially examined, because the developments of these years determined the pattern of activity of subsequent decades.

DWIGHT R. LEE, Ph.D. California (San Diego) 1972. Dynamic profit maximization under conditions of monopoly.

The basic problem considered is that faced by a monopolist attempting to schedule the production, sales, and inventory holdings of his product over an N-period interval of time in such a way that profits are maximized. The demand schedule faced in each period is assumed known. The solution is restricted by the following constraints: inventory holdings; production and sales must be nonnegative in all periods; and the final inventory must be some specified amount. Only very general restrictions are imposed on cost and demand functions.

EDWARD C. LESNICK, Jr., Ph.D. Notre Dame 1973. A quantitative analysis of the supply and demand for ships: A case study of colonial New York and South Carolina.

The dissertation is a study of the maritime industries of the eighteenth century with the colonies of New York and South Carolina as case examples. Specific objectives are: first, to analyze the supply and demand for ships; second, to organize data and to test certain statistical hypotheses; third, to develop a theoretical model which is capable of being empirically tested; and fourth, to discuss instrumental factors in the economic growth of the colonies.

MICHELLE B. MCALPIN, Ph.D. Wisconsin (Madison) 1973. The impact of railroads on agriculture in India, 1860–1900: A case study of cotton cultivation.

CHARLES P. MCPHERSON, Ph.D. Chicago 1972. Tariff structures and political exchange.

Tariff legislation is viewed as a commodity bought and sold in a market. It is purchased by economic groups in a society (producers or consumers) and is sold by a firm called the political system. A theoretical model of this market is developed and empirical implications are drawn. Cross-sectional and cross-time tests are carried out relating 1954 and 1958 tariff data to industry census data for a number of manufacturing industries. The results are inconclusive.

RICHARD S. MACK, Ph.D. Colorado State 1972. Social rationality and consumer behavior.

ROBERT J. MACKAY, Ph.D. North Carolina 1972. Monetary growth models.

CHARLES F. MANSKI, Ph.D. Massachusetts Institute of Technology 1973. The analysis of qualitative choice.

JAMES R. MARCHAND, Ph.D. Virginia Polytechnic Institute 1973. Two essays on externalities in supply.

This is a dissertation in two distinct but somewhat related parts. The first part of the dissertation analyzes the literature on externalities in supply before World War II. The second part of the dissertation pursues the topic of interindustry externalities in supply through the author's own analysis of this problem.

WARREN T. MATTHEWS, Ph.D. Texas A&M 1972. An empirical test of a theory of spatial pricing.

This dissertation is an empirical test of Greenhut's theory of spatial price structure. Using the concept of cost-imposing economic space between buyer and seller, it is deduced that the firm will practice price discrimination in favor of more distant buyers. The pricing policies of 1200 firms are analyzed to study the impact of costly economic space on spatial price structure, and implications of the theory for *U.S.* antitrust policy are examined.

CRAIG A. MEDLEN, Ph.D. California (Santa Barbara) 1973. Problems of proletarian class consciousness in the writings of Karl Marx.

KENNETH B. MOBERG, Ph.D. Purdue 1972. Individual and social decision processes.

CLAIR E. MORRIS, JR., Ph.D. Wisconsin (Madison) 1973. J. Laurence Laughlin: An economist and his profession.

This is an assessment of Laughlin's contributions to the economics profession with emphasis on his role in the monetary debates of the 1890's and the money reform movement leading to the passage of the Federal Reserve Act of 1913. Attention is also given to his rivalry with Richard T. Ely and the impact which he had on the founding of the "Chicago School."

ANJAN MUKHERJI, Ph.D. Rochester 1973. On the stability of competitive equilibrium.

It is possible to extend and clarify the existing results on the stability of the competitive equilibrium in several directions. The following are treated: a successive tâtonnement where only the good with the largest excess demand has its price raised; extensions of the gross substitute system to include complementarity; stabilizing income effects; variable speeds of adjustment; convergence of prices in a barter framework; dependence of stability results on the choice of numeraire.

JURGEN MÜLLER, Ph.D. Stanford 1972. The impact of information on technical efficiency.

The concept of technical efficiency differences—different levels of output with identical levels of input—is unsatisfactory from a production theoretic point of view. Here we develop a model in which differences in nonconventional inputs and especially information obtained by managers may explain productivity differences between firms. Estimation of the underlying production structure (of a sample of California dairy farms) via a modified nonhomothetic Cobb-Douglas production function show the specific impact of information.

PAUL F. MULLIGAN, JR., Ph.D. Duke 1973. Government functions in an underdeveloped free enterprise economy: The economic system of Liberia.

IWAO NAKATANI, Ph.D. Harvard 1973. Essays in economic theory: Uncertainty, ability, and social welfare.

The thesis consists of three essays. The major theme in all three essays is the analysis of the impact of the existence of uncertainty on the level of individual welfare, where individuals are different with respect to ability, income, and value systems, generally. It is argued that uncertainty is an important source of inequalities of many dimensions. Welfare implications for various classes of individuals which arise from such differences are examined from various aspects.

WAYNE F. PERG, Ph.D. Purdue 1972. Theoretical foundations of macroeconomics.

PIERRE M. PESTIEAU, Ph.D. Yale 1972. Optimal public investment and rate of discount.

GLENN C. PICOU, Ph.D. North Carolina (Chapel Hill) 1972. The neoclassical model of optimal capital demand.

ALAN M. POLINSKY, Ph.D. Massachusetts Institute of Technology 1973. Essays in public sector economics: Central and local.

CLAYNE L. POPE, Ph.D. Chicago 1972. The impact of the antebellum tariff on income distribution.

This thesis examines the impact of the antebellum tariff on income distribution between North, West, and South. A general equilibrium model is constructed which incorporates relevant features of the antebellum economy—intermediate goods, nontraded goods, and factor immobilities. The results of combining plausible structural data with the model indicate that a general increase in tariff rates would redistribute income from cotton planters to manufacturers. However, a tariff increase on cotton textiles reversed this result.

HARVEY J. REED, Ph.D. Purdue 1973. An experimental study of equilibrium in a competitive market.

Equilibrium has been used as a maintained hypothesis in the estimation of supply and demand curves. However, to date little experimental evidence exists for a nontâtanoment process. This thesis attempts to test the zero excess demand hypothesis against an alternative hypothesis which is constructed from a Bayesian learning model for individuals. At least for a small number of periods, equilibrium in the sense that supply equals demand can be rejected in favor of the Bayesian learning model. However, little is known about the consequence of running many more periods.

SCOTT F. RICHARD, D.B.A. Harvard 1972. Optimal life insurance decisions for a rational economic man.

The problems of an individual who is periodically faced with consumption, investment and life insurance decisions are analyzed with a decision theoretic framework. A proper joint utility for consumption streams, legacy, and lifetime is derived under certain behavioral assumptions, and shown to be of product form. For both analytical and numerical formulations of the problem, optimal consumption, investment, and life insurance policies are found by using stochastic dynamic programming to maximize the investor's joint utility.

RICHARD ROMANO, Ph.D. State University of New York (Binghamton) 1973. Dissension within the English classical school: An integration of the thought of William F. Lloyd.

This thesis examines the Oxford lectures (on population, poor-laws, value, rent) of W. F. Lloyd (1794–1852); compares him with Ricardo, McCulloch, James Mill, and dissenters like Bailey, Scrope, Jones; and suggests his lack of influence may have been due in part to a social outlook which often placed him at odds with the process of industrialization and associated him with the views of Paley, Malthus, Jones, and Coleridge, rather than the Ricardians.

JANE L. ROSS, Ph.D. American 1972. A quantitative study of the historical development of England, 1600–1960.

LEONARD G. SAHLING, Ph.D. Michigan 1972. The price equation: An econometric study.

YASUHIRO SAKAI, Ph.D. Rochester 1937. Axiomatic foundations of consumption and production theories.

This study examines four topics: equivalence of the weak and strong axioms of revealed preference without demand continuity assumptions; axiomatic foundations of the indirect utility function, based on the revealed preference approach; an axiomatic approach to input demand theory when a firm produces only one output; substitution and expansion effects in the general case of joint production.

LEE W. SAMUELSON, Ph.D. Harvard 1972. Portfolio theory and the theory of the firm: An investigation of firms' asset management behavior under risk.

Firms are viewed as managing portfolios of assets—both real productive assets and financial assets. A portfolio model of firms' asset management behavior is developed, based on approximate closed form solutions for myopic multiperiod portfolio optimization in the absence of a risk-free asset. Empirical investigation of the model leads to the conclusion that firms' asset management policies are considerably more conservative than would be expected if maximization of (expected) geometric rate of return were their objective.

PHILLIP M. SARVER, Ph.D. Nebraska 1972. Historical influences on the economy of Pueblo, Colorado.

This dissertation (1) examines those critical aspects of growth which have acted to promote or retard the development of the economy; (2) offers an explanation of the present condition of the city; and (3) explores the prospects for the future growth of the community. Although there is now a favorable trend toward greater growth, unless the obstacles which the people themselves have created are overcome, the economic growth will be slow.

MARK A. SATTERTHWAITE, Ph.D. Wisconsin (Madison) 1973. The existence of a strategy proof voting procedure: A topic in social choice theory.

The dissertation considers committees whose task is to select one alternative from a set of three or more alternatives. Committee members cast ballots which are counted by a voting procedure. The voting procedure is strategy proof if it always induces every rational committee member to cast a ballot that reveals his preferences. The main theorem proved states that no strategy proof voting procedure exists that satisfies the Pareto principle and is not dictatorial.

WAYNE J. SHAFER, Ph.D. California (Santa Barbara) 1972. Two essays in mathematical economics.

LAURENCE SHUTE, Ph.D. Columbia 1973. The economic thought of John Maurice Clark: Toward the development of social economics in the United States.

This thesis is a comprehensive study of Clark's works. Pioneering in the institutionalist tradition, his prodigious output spanned a broad range of economics and yielded significant contributions to the formulation of a social, dynamic theory of economic process. Much of his work is now classic: Overhead Costs, Effective (workable) Competition, Multiplier, and Accelerator Analysis, for instance. Nevertheless, there remains a great deal which has not yet found its way into the mainstream of orthodox thought.

AUSTIN SPENCER, Ph.D. Indiana 1973. An examination of relative downward industrial price flexibility, 1870–1921.

This study examines the hypothesis that industries that experienced increased concentration over the period 1870–1921 show a decline in price flexibility, while industries which did not experience increased concentration show no observable reduction in price flexibility. Price data to test this hypothesis were collected for eleven industries that experienced structural change and for two groups of products of industries that remained competitive throughout this period. Comparable price data were collected for New York, Philadelphia, and Cincinnati.

J. R. STANFIELD, Ph.D. Oklahoma 1972. The economic surplus and neo-Marxism: A further revision.

This study is a contribution to the neo-Marxist literature on modern capitalism. The fundamental theme is that neo-Marxism has thus far failed to repudiate sufficiently the competitive law of value. The economic surplus, defined as potential output minus essential consumption, is estimated for the 1929–1970 period, from time-series. These estimates are then used to evaluate certain aspects of neo-Marxism. The major conclusion is that emphasis should be placed upon the composition rather than the level of total output.

IVAN STARKE, Ph.D. Washington 1973. Policy implications of factor and commodity taxes in general equilibrium.

RICHARD J. SWEENEY, Ph.D. Princeton 1972. Firm decision making, and macroeconomic disequilibrium.

In an economy where each of many firms is a monopolist-monopsonist, aggregate business sector decision functions relate *actual* prices and wages and business' *desired* investment, hiring and growth to aggregate demand, the interest rate, expected price and wage inflation, and the aggregate rate of unemployment. Short-run policy recommendations include high aggregate demand to spur growth and hiring, and a low interest rate to mitigate inflation from the cost side.

KATSUAKI TERASAWA, Ph.D. Kansas 1972. Optimal replacement timing and pricing policy of a house.

WILLIAM J. WEEKS, Ph.D. Kansas 1972. An Evans-Roos model for the dynamics of the firm.

The Evans-Roos dynamic models of monopolistic and competitive markets published during the 1920's are the first attempts to apply the calculus of variations to economic theory. The relative obscurity of their work is due to the limited applications of the type of demand curve specified, and to the scanty qualitative information which they extracted from the model. This dissertation is concerned with characterizing the optimal paths of price and quantity under various assumptions about cost and demand conditions. It also develops an alternative dynamic monopoly model for a Wicksteed-type demand curve.

WILLIAM E. WEHRS, Ph.D. Purdue 1972. Incomplete specification and aggregation in a class of econometric inventory investment models.

A class of Accelerator-Buffer Stock models modified for production flexibility is examined with regard to an apparent inconsistency between estimates of two structural parameters. A more complete rational model, consistent with this class, is specified. The expression of the two structural parameters as functions of parameters in the more complete model allows an explicit analysis of the apparent inconsistency. Simulation results tentatively indicate that aggregate coefficient estimates provide little information on micro behavior.

JOHN A. WHIPPEN, JR., Ph.D. Colorado State 1972. Economic and social change.

This study is concerned with the process of trans-

formation of value and institutional parameters as they are reflected in established Western thought. It is proposed that theory is derived from the behavioral norms of society; as these norms evolve theory must also evolve. The key hypothesis of the study is that the positive methodology in economics is conducive to the growth of theory which is incapable of adjusting for value changes in society.

BETTY D. WICKHAM, Ph.D. Rochester 1973. Some operational implications of a linear consumer production model with fewer characteristics than goods.

This paper extends the Lancaster consumer-producer model operationally. It is argued that the existence of linearly related goods implies ruled indifference surfaces and that these relationships can be measured when goods prices cause entire rulings to be efficient. Circumstances leading to this result are examined along with a procedure for estimating the number of characteristics and the objective structure among goods. Finally, a procedure for choosing unique characteristics is proposed.

WILLIAM D. WILLIAMS, Ph.D. Union Graduate School, Antioch 1972. The mathematics of Veblenian economics.

The work of Thorstein Veblen is commonly thought of as fundamentally unsystematic and incapable of mathematical representation. A demonstration is made that a systematic presentation is possible. The essential core of Veblen's thought is the insistence that the fundamental features of economic theory be formulated in terms of change rather than in terms of stationary states. Mathematical representation takes the form of differential equations involving time rates of change of economic variables.

DANIEL P. WILLIAMSON, Ph.D. California (San Diego) 1973. A differential game version of the entry barrier problem.

This dissertation examines the behavior of a monopoly concerned with preventing entry into its market. An entry decision will be based upon the profitability of the postentry duopoly market. The problem of measuring a barrier to entry is that of determining a link between preentry monopoly characteristics and this postentry duopoly profitability. The duopoly problem is analyzed as a dynamic, two person, cooperative game. A key component of such games is the formulation of noncooperative threat strategies which help determine the final arbitrated outcome.

MICHAEL L. WISEMAN, Ph.D. Wisconsin (Madison) 1972. An essay on household investment.

CHRISTINE N. WOLLAN, Ph.D. Illinois (Urbana) 1972, The financial policy of the Soviet State Bank, 1932–1970.

JESS B. YAWITZ, Ph.D. Washington (St. Louis) 1972. Economically relevant wealth: Its specification and role in consumption.

This study investigates the appropriate specification of the wealth variable in the aggregate consumption function. This endeavor is important for domestic stabilization policy, since both the built-in stabilizers and the responsiveness of the economy to policy decisions depend upon how wealth affects consumption. After rejecting the cash balance hypothesis, I measure the net worth contribution of both the federal debt and the money supply. I conclude that the entire debt should be included in household net worth, but only the conventional specification of outside money is relevant for the wealth effect.

JANG HEE YOO, Ph.D. Texas A&M 1972. The general disequilibrium and market adjustment mechanisms in macroeconomic models.

A mathematical model for the general disequilibrium is established recognizing the inflexibility of the price variables. It includes the commodity, bond, and labor market. In particular, Patinkin's spillover effects and Clower's dual decision hypothesis are integrated in the model, and Tucker's disequilibrium model is extensively revised by modifying the concept of the spillover variables. Using this alternative model, the signs applicable to change in the price variables in the various cases of disequilibrium are investigated.

RICHARD M. YOUNG, Ph.D. Pennsylvania 1972. Macro decision making under uncertainty: Some theoretical and simulation results.

Economic Growth and Development; including Economic Planning Theory and Policy, Economic Fluctuations and Forecasting

GEORGE O. ABALU, Ph.D. Iowa State 1973. Optimal investment decisions in perennial crop production in Cameroon: A dynamic programming approach.

Agricultural administrators in developing countries are increasingly involved in making investment decisions within the framework of their national development programs. The dissertation was designed to make some modest contributions to our understanding of (a) the nature of optimal investments in perennial crops, (b) the economic organization of perennial crop production, and (c) the effects of allowing for possible divergences between observed and actual measures of costs and benefits on investment strategies for perennial crop production in Cameroon.

GEORGE T. ABED, Ph.D. California (Berkeley) 1972. Industrialization, employment growth, and economic development (with special reference to the case of Egypt).

ABDEL R. ABDEL-WAHAB, Ph.D. Illinois (Urbana) 1972. Tax policy and problems in a developing economy: A case study of the Sudan.

BASHIR AHMAD, Ph.D. Michigan State 1972. Farm mechanization and agricultural development: A case study of the Pakistan Punjab.

MUSHTAQ AHMAD, Ph.D. Indiana 1972. Production functions in West Pakistan agriculture.

This study focuses on the agricultural crop sector of West Pakistan during the period from 1950–51 to 1960–61. Cobb-Douglas production functions are estimated for both years with cross-sectional data. Land and labor were optimally used in 1950–51 and land and irrigation were almost optimally used in 1960–61. The output elasticity of land has greatly increased whereas those of irrigation and labor decreased. These changes are mainly due to the relative increases in respective quantities. The study suggests that government development of the crop sector should have been based on a greater use of chemical fertilizer and other biological inputs, which increase the per acre yield and substitute for the scarce input of land.

RAIS U. AHMED, Ph.D. Michigan State 1972. Economic analysis of tubewell irrigation in Bangladesh.

CHOONG-YONG AHN, Ph.D. Ohio State 1972. A recursive programming model of regional agricultural development in southern Brazil (1960–1970): An application of farm size decomposition.

M. ATAMAN AKSOY, Ph.D. Boston College 1973. Growth and trade in a two-sector model with nonshiftable capital and endogenous technological change.

GEORGE ALIBARUHO, Ph.D. California (Berkeley) 1973. Effects of marketing board policies on prices, production, and income in Uganda's cotton industry.

GARTH O. ALLEYNE, Ph.D. California (Los Angeles) 1972. A linear programming model of educational planning for Trinidad and Tobago, 1968–1975.

GERHARD ANDERS, Ph.D. Texas A&M 1972. On the economic development of Canada's North West Territories.

Canada spent $80 million annually for NWT development without studying basic economic problems. The dissertation traces how attenuation of property rights among natives modifies income-leisure indifference curves, and yields a negatively sloped labor supply curve. This explains native labor market participation with transfer payments availability. I analyze the influence of a transcendentalist or immanentist worldview on model construction and the determination of policy constraints. Development theories are criticized in light of preceding, and policy recommendations follow.

ROY D. ANDERSEN, Ph.D. Illinois (Urbana) 1972. The financing and allocation of public expenditures in Sierra Leone.

MICHAEL B. ANDERSON, Ph.D. Cornell 1973. A model of the small Chilean firm.

EDWIN K. A. ANG, Ph.D. California (Berkeley) 1972. The use of a social accounting framework of economic growth for long-range projections of the Taiwan economy, 1970 to 1979.

JALAL M. A. BAYATI, Ph.D. Southern California 1973. Appraisal of developmental planning and industrialization in Turkey.

The successes and failures of Turkish economic planning are appraised by analyzing the development of basic industries including mining, iron, steel, and electricity. Each sector is evaluated either by measuring the relative efficiency of total investment in each industry or the returns attributed to the total investment, depending on the availability of data.

ASSEFA BEQUELE, Ph.D. Indiana 1973. Industrialization and labor absorption: Projections for Ethiopia, 1968–1983.

Within the context of the Ethiopian economy, this dissertation examines the interrelations between pace of industrialization and the rates of absorption of surplus labor from agriculture under assumptions concerning population growth, urban expansion, and increases in labor productivity. Required levels of industrialization and values of other macroeconomic variables consistent with exogenously determined rates of growth of employment are defined within the framework of a two-sector projection model based on Harrod-Domar, Mahalanobis, Ichimura, and Chenery models of growth and planning.

RICHARD E. BERNSTEIN, Ph.D. Brown 1973. Factor allocation in tropical agriculture: A theoretical and empirical analysis.

This study analyzes the efficiency of factor utilization on farms of different size and tenure in Brazil and Cuba. Comparisons were based on factor marginal products derived from estimated Cobb-Douglas production functions. The effects of inflation on farm ownership were included in the Brazilian analysis. Data were obtained from agricultural censuses of the two countries. Results demonstrated constant monopsonistic behavior on the part of large landowners.

HANS P. BINSWANGER, Ph.D. North Carolina State 1973 The measurement of biased efficiency gains in United States and Japanese agriculture to test the induced innovation hypothesis.

The hypothesis that biases in efficiency gains arising from technical change and other sources are endogenously determined by economic forces rather than exogenously determined was supported by this analysis. Estimating equations for biases in the many-factor

production case were developed using a transcendental logarithmic cost function in factor augmenting form, making it possible to divide observed share changes into a component due to efficiency gains and a component due to price changes. Components due to efficiency gains were then used to construct indices of biases which were markedly different in the *U.S.* and Japanese experience during the twentieth century.

BARBARA M. BISCO, Ph.D. Cornell 1973. Constraints on economic growth: A case study of the Thai rubber industry.

DAVID G. BLANCHARD, Ph.D. Indiana 1973. The impact of external domination on the Liberian mano economy: An analysis of Weber's hypothesis of rationalism.

Max Weber points out that the history of European economic development has been the gradual shift from the traditional (patriarchal and patrimonial) towards the more rational legal domination of economic life. To test Weber's hypothesis this study considers a small group of West African tribes in Liberia who have in the last fifty years begun a shift from a traditional, autonomous, and closed household economy to a peasant and wage-labor economic order operating within a national, political, and bureaucratic domination. A major conclusion is that the transition from traditional to market economy has been speeded up because of outside influences coming primarily from the United States.

WILLIAM A. BOMBERGER, Ph.D. Brown 1973. An error analysis of optimal stabilization policy.

An examination of the performance of various formulations of stabilization policy focusing on the performance of policy in the presence of errors in the policy maker's perception of the economic mechanism. A series of econometric models are selected from the literature and reestimated. Various forms of stabilization policy formulation are derived and their performance simulated in the case in which such a policy is executed by a policy maker who perceives the economic mechanism in the form of one model in a world described by another model or by a model which differs from that of the policy maker in parameter values or lag structure.

JORGE O. BONVICINI, Ph.D. Louisiana State 1972. Cycles in demand-pull inflation: An econometric approach.

SALAH A. BOURJINI, Ph.D. Kansas 1972. Sources of economic growth in developing countries: The case of Tunisia.

RICHARD T. BURCROFF, Ph.D Washington 1972. Contractual choice in Philippine rice farms: Implications for land reform in Asia.

GILES BURGESS, Ph.D. Oregon 1973. A study of modern economic growth using estimates of aggregate production functions for six nations, 1870–1914.

SUTHIPORN CHIRAPANDA, Ph.D. Iowa State 1972. Linear programming models of interregional competition for economic planning of Thai agriculture.

Two major regional planning models for Thai agriculture have been formulated. They are operational but, due to the lack of data, are not applied. The first deals with the short run, utilizing as little uncollected data as possible. It aims to minimize the costs of commodity production, processing, and transportation, subject to land resource constraints and demand requirements. The second model is an extension of the first, involving several resources. It is applicable in the long run. Several policy implications have been made, including water resource development.

KWONG-YUAN CHONG, Ph.D. Michigan State 1973. A simulation policy analysis of the Western Nigerian cocoa industry.

ROGER N. CRAINE, Ph.D. Maryland 1972. Forecasting, adjustment costs and factor demands: Or the emperor's clothes.

This paper constructs a dynamic model of the firm. The demand for four factor inputs—capital, employment, average hours, and the change in inventories—were derived form the theoretical model. The factor demand equations depended on future values of the exogenous variables, which were forecast by the firm. The forecasting procedure gave a distributed lag model in which the weights represented a convolution of the forecasting weights and the weights from the adjustment cost model. Several variants of the model were estimated using a Zellner-Aitken technique to impose restrictions across equations.

ROBERT W. CROWN, Ph.D. Iowa State 1972. A model of income distribution by size-class with application to the results of technical change.

A model is developed that aggregates consistently from the welfare of individuals to that of classes, and a link is made between the derivation of welfare and the participation in factor markets. Two distributions are observable, the functional income and the personal welfare distribution by class. In an application to a district agricultural economy of India, the model is quantified only up to income levels, thus showing the distribution of personal income by class. The impacts of technical change on this income distribution are observed, as are the results of experiments with policy alternatives aimed at attaining equity of income distribution.

JEAN EMILE DENIS, D.B.A. George Washington 1971. The structure of private consumption in selected Latin American countries.

In addition to income level, four other socioeconomic factors are taken into account: relative price structure (for food only), urbanization level, income distribution, and foreign trade. Data on the variables are drawn from published sources, mainly from the UN and ECLA publications. The statistical technique used is a derivation of Venn diagram analysis. It is found that by taking into account the four factors other than income a much better understanding of consumption is achieved than when income level alone is taken into consideration.

FELIX DIAZ-LOPEZ, Ph.D. Southern California 1973. The role of government in industrial development: The case of the Commonwealth of Puerto Rico.

This inquiry examines the role of government in the process of economic progress. Puerto Rico's successful experiment with industrial development provides empirical insights concerning the importance of government as a source of critical inputs to the process of growth. Findings suggest that development policies when properly formulated within a given political and institutional framework, as in the case of the Commonwealth of Puerto Rico, are generally capable of effecting the socioeconomic readjustments necessary for growth.

PAUL H. EARL, Ph.D. Georgetown 1972. An analysis of industrial price behavior.

This dissertation is concerned with the specification, estimation, and simulation of equations to explain price behavior in a representative sample of twenty-two *U.S.* manufacturing industries. The price equations contain cost-based and excess demand pricing hypotheses, derived primarily from competitive and oligopolistic theories. Estimation is by ordinary least squares on data from 1958 to 1969, while simulations are run from 1965 to 1969. Alternative inflation policies with targets consistent with the Economic Stabilization Program are tested in an *ex post* fashion.

LEYLA ECEVIT, Ph.D. Pittsburgh 1972. Structural changes, production functions, and economic development in Turkish manufacturing.

A study of Turkish industrialization during 1950–68. Structural changes across countries and over time are used as a base for comprehensive comparisons with Turkey at the three aggregate sector level and for individual manufacturing industries. Production function analysis is used to identify the relative contribution of various factors of production to changes in output, to differentiate between the performance of the public and private sectors, for preplan and postplan periods.

VASSILIKI ECONOMOPOULOS, Ph.D. Nebraska 1972. A linear programming model and its application to the Greek economy.

This is an investigation of the effects of selected education and manpower policies upon the output of the Greek economy. Using empirical data, the study combines the methods of input-output analysis with those of parametric linear programming analysis. The study reveals the usefulness of such a procedure in policy analysis and implementation.

RICHARD E. EDDY, Ph.D. Illinois (Urbana) 1972. Measuring levels of living.

THOMAS EDENS, Ph.D. Michigan State 1972. Fluctuations in foreign exchange reserves and in the volume of construction: The similarity between industrialized and nonindustrialized countries in 1870–1914 and their divergence in 1955–1968.

This thesis examines the relationship between foreign exchange reserves and the volume of construction in industrialized and nonindustrialized countries. The hypothesis that construction in nonindustrial countries is more sensitive to exchange reserve fluctuations than in industrialized countries is supported by a cross-sectional time-series test. While the development of financial intermediaries to supply funds for housing construction appears to promise employment and better living conditions in the developed countries, this trend may also increase the instability of the construction sector.

AHMED EL-DERSH, Ph.D. Syracuse 1973. Economic sectoral structure, economic policy, and foreign trade: The case of Egypt, 1952–1964.

The subject of this study is the Egyptian economy in the period 1952–64. The purpose of the study is to trace the changes in Egypt's sectoral structure and economic policy and to relate them to changes in its foreign trade sector. The period is divided into three phases: The Free Enterprise (1952–56), The Mixed or Guided Capitalism (1957–60), and The Socialist Central Planning (1961–64).

ULRICH ERNST, Ph.D. Indiana 1973. Human resources in regional economic growth.

The study examines the interactions between human resource formation and economic development in a hypothetical two-region economy. The analysis is based on a series of simulation, with a digital-computer model. This model builds on the microeconomic behavior of three groups of decision makers: students enrolled in the educational system who choose between continuing their education and entering the labor force; individuals employed in one region who choose between staying in that region and migrating to the other; and individuals controlling the regional allocation of investment.

DANIEL C. FALKOWSKI, Ph.D. New York 1972. Nacional Financiera, S.A., de Mexico: A study of a development bank.

As one of the oldest and most successful development banks in the world, Nacional Financiera provides the basis for a case study of one such institution. NAFIN is a unique institution and is as much a product of Mexico's growth experience as it has been a causal factor. Nacional Financiera's outstanding

achievement has been its success in stimulating the development of the domestic financial markets.

MONDHER GARGOURI, Ph.D. Cornell 1973. Experiments with a dynamic multisector planning model for Tunisia.

NEIL H. GARSTON, Ph.D. Brown 1973. Economic growth and human capital: A theoretical and empirical study.

A two-sector, two-factor, real variable growth model is developed; the factors being physical and human capital. One sector produces consumer goods and physical capital; the other, human capital. With rational investment, the equilibrium growth path is determined by all parameters of the system, including the savings ratio. The model is applied to some available data for the United States since 1929, factor shares in the sectors are derived, and long-run growth rates projected.

JUAN A. GIRAL-BOSCA, Ph.D. Yale 1973. Allocation of resources through planning: The Ecuadorian experience.

LORETTA L. GOOD, Ph.D. Cornell 1972. United States joint ventures and national manufacturing firms in Monterrey, Mexico: Comparative styles of management.

Comparative analysis indicated that growth rates and profitability between 1960 and 1969 were very similar for the two groups. However, the most powerful variables which explained an unusually high degree of within-group variance in performance for the joint venture firms were: distribution of internal financial resources; equity patterns; and investment patterns. However, for the Mexican firms they were: sources of technical information; productivity consciousness; and marketing practices.

EMIL O. HERBOLZHEIMER, Ph.D. Michigan State 1972. Cross-section analysis of demand for housing in Venezuela.

The major part of the thesis is designed to determine statistically the most important socioeconomic variables and the value of their parameters with respect to demand for housing in Venezuelan urban areas. Of particular interest is the elasticity of income and of mortgage terms. Tastes and preferences of household heads are analyzed as well as the employment created by the construction of different types of housing units. The data were drawn from three household surveys and mortgage loan applicants.

HENRY HERTZFELD, Ph.D. Temple 1973. Thresholds of regional development in the residentiary industries of the United States.

EKRAM HOSSEIN, Ph.D. Tufts 1973. An econometric analysis of the economic structure and planning decisions in Bangladesh.

WALLACE E. HUFFMAN, Ph.D. Chicago 1972. The contribution of education and extension to differential rates of change.

This econometric research analyzes differential adjustments to disequilibria. The hypothesis that adjustment rates vary positively with decision maker's information levels is tested by fitting a variable adjustment coefficient model between 1959 and 1964 to *U.S.* county aggregate data on nitrogen fertilizer consumption. Measuring information as levels of farmers' education and of agricultural extension activity, the estimated model supports the hypothesis. Increasing education (extension) increases the adjustment coefficient's size; however, increasing education reduces extension's contribution.

THOMAS L. HUTCHESON, Ph.D. Michigan 1973. Incentives for industrialization in Colombia.

PATRICK P. JEANJEAN, Ph.D. California (Berkeley) 1972. Optimal growth with stochastic technology in a multisector economy.

U-JIN JHUN, Ph.D. State University of New York (Albany) 1973. Investment in nonresidential construction in the United States—an econometric study of quarterly time-series—1954–65.

This study develops and estimates investment functions for types of nonresidential construction: industrial, commercial, hospital, educational, religious, and recreational. It makes use of quarterly time-series data for the years 1954–65. The underlying determinants of these types of construction vary considerably, particularly with respect to methods of financing. Unlike residential construction, a separate investment

function is necessary for each component of nonresidential construction.

MUHAMMAD B. M. J. KABBARAH, Ph.D. American 1972. Scope and sequence of industrial development in Syria: An economic analysis.

GOPAL K. KADEKODI, Ph.D. Southern California 1973. Planning for stability and self-reliance: An evaluation of policy approaches for India.

A comparison of two policy models for India suggests that insufficient savings and inelastic demand for investment are the most serious barriers to development. Foreign investment is shown to be usually undesirable because it hurts the balance of payments. India should have the government set guidelines for investment. A two-sector model shows that properly allocated government investment can insure the attainment of a full employment stable growth path in less than fifteen years.

ASMERON KIDANE, Ph.D. Pennsylvania State 1973. The demand and price structure of selected food products in Ethiopia: An econometric and spectral analysis.

YOUN-SUK KIM, Ph.D. New School 1973. Postwar Japan's foreign trade (1945–1965) and its lessons for developing countries.

Granted that pre-World War II Japan was a formidable industrial country, it still seems justifiable to concede that she could never have made the enormous strides she has taken had she not worked out a very innovative strategy concerning foreign trade. Thus, it is not Japan the industrial nation, but Japan the trade strategist that is the focus of this dissertation. It is the trade strategist that may have much to offer in the way of an example to developing economies.

WERNER LACHMANN, Ph.D. Rutgers 1972. Education and growth: A control theoretic approach.

Most growth models grow at an exogenously determined growth rate. Through the introduction of an education sector which produces technical progress with the help of capital and manpower, the growth rate is internalized. The maximum principle is used to solve the optimization problem. It is shown that the steady state is the optimal state. The disequilibrium analysis shows that a saddlepoint exists and that the optimal control leaks back to the steady state.

OLASUPO O. LADIPO, Ph.D. Michigan State 1973. General systems analysis and simulation approach: A preliminary application to Nigerian fisheries.

JAMES J. LAKSO, Ph.D. Maryland 1973. A technique for choosing between direct foreign investment and domestic investment in production for sale in the domestic market in developing countries.

The dissertation suggests a general, simple decision technique which developing countries can use to evaluate particular kinds of direct foreign investment. The operational basis of the technique is a benefit-cost ratio which compares the benefits and costs of foreign ownership compared to domestic ownership of the same production process. A case study of a foreign investment in South Korea illustrates the applicability of the technique and its sensitivity to the decision variables.

JOHN S. LANE, Ph.D. Stanford 1972. Optimal economic growth and endogenous population change.

In the context of an optimal economic growth model a synthesis of the Ramsey-Meade rules has been presented and the implications examined for an optimal joint savings/population policy. The model used was the Ramsey model with discounting but modified to allow the population growth rate to be determined by per capita income.

JAMES F. LEVINSON, Ph.D. Cornell 1972. An economic analysis of the determinants of malnutrition among young children in rural India.

This research was interdisciplinary in nature examining nutrition and health factors together with economic variables in an attempt to determine more precisely the causes of malnutrition in 6–24 month old children in rural India. Economic status was clearly a most important variable, but improvement in economic status alone would in many cases not improve the nutritional status. The role of educational programs is critically analyzed within the model developed.

WUU-LONG LIN, Ph.D. Stanford 1973. Economic interactions in Taiwan: A study of sectoral flows and linkages.

In Taiwan agricultural development has complemented rapid industrialization as the predominantly agricultural economy has been transformed into a modern diversified economy. This study examines the interaction between agriculture and industry in linkage effects and resource outflow from the agricultural sector during the period 1952–70. Findings are that agriculture can provide momentum for economic growth; the small-scale farm system was able to achieve high agricultural productivity by using labor-intensive and capital-saving technology.

CHUNG-CHI LU, Ph.D. Iowa State 1973. The role of food aid, agricultural development, and capital for-

mation in economic development: A case study of Taiwan.

The major concern of this study was the growth in Taiwan's agricultural output, the formation of capital, the means by which the increased agricultural output was attained, and the role of American food aid in this process. The specific objectives of this study are: to examine economic development of Taiwan's agriculture since World War II and the role of agricultural sector in capital formation; and to appraise and analyze the economic effects of American food aid program in aiding economic development of Taiwan's agriculture.

ANTHONY M. MARINO, Ph.D. California (Santa Barbara) 1972. A two-sector model of growth with asymmetrical productive processes.

JUAN C. MARTINEZ, Ph.D. Iowa State 1973. On the economics of technological change: Induced innovation in Argentine agriculture.

The central objective of this study is to attempt to identify the factors influencing the demand for and supply of agricultural innovations, providing additional explanation for the relative stagnation of the agricultural sector in Argentina for the last decades; in particular, emphasis is given to the Pampean region. The analysis tries then to explain the process of generation of agricultural innovations by public and private institutions and the adoption of the new technologies by the farmer.

AGOGO MAWULI, Ph.D. Illinois (Urbana) 1972. A sensitivity analysis of balance of payments and economic expansion in less developed economies.

CADMAN A. MILLS, Ph.D. Boston College 1973. Development under the minimum time objective; Ghana under Nkrumah.

ESSAM MONTASSER, Ph.D. Princeton 1972. Egypt's pattern of trade and development: A model of import substitution growth.

The study is concerned with Egypt's import substitution growth, the factors underlying its deceleration, and the design of alternative strategies capable of restoring sustained growth. A macro-growth model combining regression and input-output techniques is constructed and used to fulfill these goals. Furthermore, the import substitution growth pattern of structural change is examined through the aid of various empirical structural techniques.

RICHARD W. MOXON, D.B.A. Harvard 1973. Offshore production in the less developed countries by American electronics companies.

This thesis examines the direct investments of American companies in the less developed counties for the manufacture of products and components for sale in the United States. A behavioral model of the offshore production decision process is developed and used to predict the characteristics of products that will be selected for offshore manufacture, as well as the countries that will be chosen as plant sites. The model is tested for the electronics industry.

MOHINDER S. MUDAHAR, Ph.D. Wisconsin (Madison) 1972. Recursive programming models of farm sector with an emphasis on linkages with nonfarm sectors: The Punjab, India.

RANGANATHAN NARAYANAN, Ph.D. Yale 1973. The two-sector model of growth: An essay.

MIAN A. H. NAZ, Ph.D. American 1971. The role of the state in the development of agriculture: A case study of West Pakistan, 1950–1969.

The purpose of this study is to examine Pakistan's agricultural development experience with emphasis on the role of the state. Three hypotheses are investigated: The archaic "state of the arts" may be the reason for low productivity in agriculture; given a stable government, capable of providing the necessary resources and institutional framework, it is possible to change the state of arts and to induce increases in agriculture productivity; and in a developing country technologically induced increases in agricultural productivity can make a significant contribution to overall economic development.

GERALD I. NEHMAN, Ph.D. Ohio State 1973. Small farmer credit use in a depressed community of São Paulo, Brazil.

MOHAMED N. NOOR, Ph.D. Michigan State 1972. The Malaysian small-holder rubber sector: Implications of ethrel stimulation and the new processing technology.

OKONKWO A. NWANI, Ph.D. Florida State 1973. The role of monetary and financial institutions in economic development of Nigeria: 1800–1970.

This study analyzes the role of financial institutions in the development of Nigeria from 1800 to present. Of particular interest was the change in these institutions before and after independence. Prior to independence the structure of banks, their geographic dispersion, and their lending policies were consistent with the support of an enclave economy. After independence there was a marked change in both the structure of banks and their lending policies.

OLABISI OGUNFOWORA, Ph.D. Iowa State 1972. Derived resource demand, product supply and farm policy in the North Central State of Nigeria.

The thesis examined the problems of farm adjustment and increased supply of output in North Central State of Nigeria. The first group of analyses focused on the level of farm income, effect of technology on scale and farm income, and the stability of sole cropping and intercropping systems under different levels of resources and technology. The second group of

analyses consisted of the derivation of resource demand and product supply functions using a combination of parametric programming and multiple regression analyses.

GABRIEL I. O. OJO, Ph.D. Iowa State 1972. An econometric-simulation model of the Nigerian economy.

In this study an econometric model describing the behavior of the Nigerian economy for the period 1951–65 was estimated. The model, which contains fifteen equations, was estimated by two-stage least squares, and was used for simulation and multiplier analysis. The usefulness of this kind of study lies in its capability of broadening the horizon of the policy maker by providing quantitative estimates of the impact of his decisions on the economy.

SUMIYE OKUBO, Ph.D. Tulane 1972. Growth, inflation, and price stability: An empirical analysis.

The purpose of the thesis is to analyze the effect inflation has on economic growth. Although it is often assumed that inflation redistributes income from non-savers to the saving group and thus facilitates growth, high rates of inflation may lead to a less efficient allocation of resources because of uncertainty and other costs associated with inflation and thus may hinder growth. Analyzing a broad spectrum of countries in various stages of development and with various degrees of inflation, we found that mild rates of inflation foster economic growth while rapid rates have a depressing effect on growth.

MARCIA MIN-RON LEE ONG, Ph.D. Ohio State 1972. Changes in farm level savings and consumption in Taiwan 1960–1970.

EMMANUEL N. ONUNKWO, Ph.D. Georgetown 1973. Sensitivity analysis in the evaluation of agricultural projects in Nigeria.

The dissertation has two main objectives. The first an examination of the concept of sensitivity analysis as a theoretical tool for the evaluation, selection, and management of projects. The second an examination of its application to projects in the agricultural sector of a developing country like Nigeria. The dissertation deals with the subject in five chapters, and contains general conclusions on the subject and specific conclusions on the Nigerian agricultural projects subjected to the study.

BOUBAKAR OUATTARA, D.B.A. Harvard 1973. The capital structure problem of development finance institutions: A case study of the Industrial Credit and Investment Corporation of India.

This study of the Industrial Credit and Investment Corporation of India examines three issues concerning development finance institutions: The relationships between capital structure and the cost of capital; lending rates and cost of capital; and the effects of borrowing limitations imposed by foreign lenders on capital structure decisions. The findings were: capital structure and cost of equity are indirectly related; no clear effects of borrowing limitations on capital structure decisions; lending rates are consistent with the cost of capital.

ROOP N. PANDEY, Ph.D. Illinois (Urbana) 1973. Livestock and crop production patterns in Uttar Pradesh, India and projections of alternative livestock development possibilities.

EFSTATHIOS PAPAGEORGIOU, Ph.D. Iowa State 1972. An econometric analysis of the structure of the Greek economy and its development prospects.

The study presents the short-term economic prospects of Greece through the application of an econometric model. First the structure of the Greek economy is examined in an attempt to identify the major constraints to growth. The projections assign considerable weight to the external sector and the sectoral composition of output, reflecting the need for changes in the pattern of output in order to eliminate the consistent and growing deficit in the balance of payments.

IBY A. PEDROSO, Ph.D. Ohio State 1973. Resource accumulation and economics of scale in agriculture—the case of São Paulo, Brazil.

PALANI G. PERIASAMY, Ph.D. Pittsburgh 1972. Economic development in India: The rationale and effects of government intervention since independence.

CLAUDIO POU, Ph.D. Iowa State 1972. Optimal allocation of agricultural resources in the development area of Patacamaya, Bolivia: A linear programming approach.

A linear programming micro-level study of cooperative farms in a setting of transition from traditional to modern forms and methods. Objectives include the determination of optimal land/person ratios, degree and path of mechanization, farm plans, level of resource use and highest achievable income per person. A comparison is attempted between these optimal conditions and the present situation. Policy recommendations are made on the basis of the results. Suggestions for further research are advanced both in agricultural economics and in other agricultural disciplines.

ABUL M. A. RAHIM, Ph.D. California (Los Angeles) 1972. Intersectual equity agricultural taxation and the strategy of economic development: A case study of Pakistan.

GHULAM M. RAHU, Ph.D. Pennsylvania 1972. The role of foreign private investment in the economic development of Pakistan.

SATISH RAICHUR, Ph.D. Pittsburgh 1972. U.S. and USSR economic and military assistance: An empirical analysis.

The study represents a systematic attempt to examine the factors affecting the size distribution of United States and Soviet aid in so far as they can be gleaned from a cross-sectional analysis of aggregate data. The U.S. and Soviet aid flows are related to the economic and political profiles of Third World countries, as well as to their relations with the two superpowers.

JAMES C. RIEDAL, Ph.D. California (Davis) 1972. The industrialization of Hong Kong.

ARCHIBALD R. M. RITTER, Ph.D. Texas (Austin) 1973. The economic development of revolutionary Cuba: Strategy and performance.

Revolutionary Cuba has pursued a changing variety of developmental objectives of an economic nature, the foremost of which have been rapid economic growth, income redistribution, the reduction of unemployment, and the reduction of external "dependence." This thesis evaluates the effectiveness of the changing policies which have been used to achieve these objectives, grouping these policies into three areas: growth strategy, mobilization strategy, and institutional strategy.

CHARLES A. ROBERTSON, Ph.D. Cornell 1973. Economic analysis of ground water irrigation in Nueva Ecija, Philippines.

The objectives of this study include: measurement of the rate of return to investment in irrigation facilities, and identification of factors responsible for variation of rates of return for an area of the Philippines. Alternative measures of rates of return to capital are discussed. Investment in shallow wells is found to be highly profitable, but investment in deep well facilities is in general not attractive.

JAMES A. ROUMASSET, Ph.D. Wisconsin (Madison) 1973. Risk and choice-of-technique for peasant agriculture: The case of Philippine rice farmers.

Several authors have suggested that the Green Revolution has not helped small farmers who are nonadopters to their proximity to subsistence and to the riskiness of modern techniques. This hypothesis is rejected by showing that a risk neutral model predicts actual fertilizer use among a group of Philippine rice farmers better than three alternate models which incorporate aversion toward the risk of "disaster." Several theoretical and methodological innovations may be of independent interest.

DONALD M. SMITH, Ph.D. Brown 1973. An application of neoclassical growth models to regional growth in the United States.

This study develops a neoclassical growth model to explain growth rates of aggregate income, employment, capital, and net migration rates. The model is tested with aggregate state data, and with sectors (manufacturing, services, agricultural) of state's output. Interregional and factor movements in response to factor price differentials cause wages in relatively low wage sectors to grow at faster rates. However, intersectoral (intraregional) factor movements may reverse this relationship.

GARY H. SMITH, Ph.D. Oregon 1972. Income and nutrition in the Guatemalan Highlands.

WILLIAM G. SNEAD, Ph.D. California (Berkeley) 1972. An economic policy model for the urban people's commune movement in the People's Republic of China, 1958–1961.

JOHN P. STEIN, Ph.D. Chicago 1973. The appreciation of paintings.

Price indices 1946 through 1968 are based on 45,000 auction prices observed in the United States and Britain. The capital asset pricing model is extended to risky durable goods. The appreciation of paintings conforms to the model when the return from nonpecuniary services is 2.1 percent per year. Paintings offer less expected return and less systematic risk than equities. Paintings are "superior" if individuals value viewing services above 2.1 percent, but substantial nonsystematic risk prevents their being "efficient."

HARRY W. STRACHAN, D.B.A. Harvard 1972. The role of the business group in economic development: The case of Nicaragua.

Business groups, long term associations of multifarious firms controlled by multiple families, dominate the private sectors of many developing countries. Their primary function in Nicaragua is financial intermediation; they facilitate both credit and investment opportunities to their members. Lesser services include intragroup business and the insurance of concentrated power. They aid capital accumulation and allocation; they aggressively establish new enterprises; but their concentrated power also brings monopolistic tendencies and other socially undesirable effects.

ESTHER C. SUSS, Ph.D. Pittsburgh 1972. An analysis of the lead-lag relationship between exports, domestic business cycles, and world business cycles: A cross-section study.

This study tries to determine what effect a country's business cycle has on its exports. Export

volume and value were analyzed for eight industrial countries from 1950 to 1970. The major statistical tool used in this study was spectral analysis. It was found that the U.S. and Canada had their export volumes promoted during domestic business expansions, and the U.S. and Austria had their export values promoted during expansions. The other countries had their exports retarded during business expansions.

'D BABATUNDE THOMAS, Ph.D. Indiana 1973. Technology transfer and capital accumulation (a study of the Nigerian manufacturing industries).

The dissertation is focused on the relationship between capital formation and technological progress with the object of determining its impact on value-added per man. The supporting data refers to Nigerian manufacturing industries.

JACOB W. VAN DUIJN, Ph.D. Illinois (Urbana) 1972. An interregional model of economic fluctuations.

SYED H. WAFA, Ph.D. Stanford 1972. Land development strategies in Malaysia: An empirical study.

Two contrasting patterns of land development in Malaysia in operation for a decade provide data for a cost-benefit evaluation. One, the Federal Land Development Authority (*FLDA*), adopted a highly regimented and closely supervised pattern and supplied more capital, technical and managerial skills, and supervisory personnel than the other. The other scheme, the Kelantan State Land Development Authority (*KSLADA*), lacking in capital and skills, relied on settlers' initiative, imagination, and dedication in opening up new land for agricultural settlement. Results of the study indicate that the settler-oriented approach of the *KSLDA* is economically more viable in terms of investment yields and of discounted cash-flow to the government. But the *FLDA* plan provides health clinics, schools, and water supply not possible with the minimal infrastructure of *KSLDA*.

PETER F. WEISEL, Ph.D. Oregon 1972. Changes in traditional agriculture: A study of three towns in northern Liberia.

THOMAS B. WIENS, Ph.D. Harvard 1973. The microeconomics of peasant economy, China: 1920–1940.

The study employs partial equilibrium, microeconomic analysis to explain the interrelationships among economic forces determining the distribution of income in a peasant economy in the early stages of transition to industrialization. Econometric techniques (regression and activity analysis) are applied to production and factor market data pertaining to the Chinese rural economy (1920–40) as a test of the accuracy of theoretical hypotheses.

AHMED H. ABDEL-RAZEK, Ph.D. Kansas 1972. The distributions of least squares estimators in the first-order stochastic difference equations.

WILLIAM E. ALEXANDER, Ph.D. Michigan 1972. An appraisal of the Hedonic approach to the measurement of quality change and a suggested modification of the technique.

AKEEL H. S. AL-SADI, Ph.D. Southern California 1972. Valuation adjustment in input-output tables, economic structure, and economic systems: A comparative empirical analysis.

The Yugoslav and Hungarian economies are compared using price adjustment models that attempt to quantify the degree of distortions in pricing and their consequent effects on the structure of these economies. Distortions in Yugoslavia appeared chiefly in transport and trade, while in Hungary, they were found in

manufacturing, agriculture, and transport. The former apparently resulted from partial price controls and market imperfections, while the latter can be attributed to administrative planning and centralization.

WILLIAM E. AVERA, Ph.D. North Carolina (Chapel Hill) 1972. A geometric mean strategy as a theory of multiperiod portfolio selection.

EDUARD H. BRAU, Ph.D. Duke 1973. A national income, trade-flow, capital-flow model of the United States and the United Kingdom: A simulation study.

WILLIAM R. CRON, Ph.D. Michigan State 1973. The demand for major household appliances: An econometric analysis.

This study attempts to examine alternative approaches to developing demand functions for three major household appliances. Two existing *ad hoc* models are studied to determine their connection with the classical utility maximization framework. Alternative models derived from the utility maximization framework are then developed. In estimating the models a procedure is developed for combining time-series and cross-section data, where the random disturbances are autoregressive, heteroskedastic, and cross-sectionally correlated.

W. ROBERT DALTON, Ph.D. Missouri 1972. Elasticities of substitution in Soviet industry.

In this paper a constant elasticity of substitution (*EOS*) is estimated for nine Soviet industrial sectors for the period 1950–69. Results for all sectors indicate that *EOS*s were significantly less than unity, and that technological change had no downward trend. The *EOS* estimates range from .081 to .671. The analysis graphically illustrates that a slowdown in the growth rate of output is implied by an increasing capital-labor ratio, and a low constant *EOS*.

WILLIAM E. JUDNICK, Ph.D. Michigan 1972. A method for modeling multinomial time-series.

GARY P. KUTCHER, Ph.D. Maryland 1972. Agricultural planning at the regional level: A programming model of Mexico's Pacific Northwest.

A programming model of the agricultural activity in Mexico's Pacific Northwest region is developed to assist in policy/planning decisions directly concerning only the region as a substitute for full sector (with regional disaggregation) analysis. The region is large enough to influence national output and input prices and the model is structured to allow for interactions with the rest of the economy through the product and input markets. Simulations of price subsidies, input subsidies, minimum wage changes, and export promotion policies are presented.

OH YUL KWON, Ph.D. McMaster 1972. Optimal fiscal strategies for economic stabilization: An econometric study with illustrative application to Canada.

The thesis is concerned with a particular methodology for applying econometric models to problems of economic policy, with illustrative applications to problems of economic stabilization in Canada during 1967–69. An annual econometric model is estimated, and a policy maker's loss function specified. Government expenditure and personal and corporation income tax rates are chosen as policy instruments. Targets are price change and unemployment. Thirty-six computer optimization experiments are reported, based on various specifications of the loss function.

KYE WOO LEE, Ph.D. Michigan State 1972. An international study of manufacturing production functions: Estimation and implications.

The thesis estimates production functions for three-digit manufacturing industries of the International Standard Industry Classification using combined international cross-sectional and time-series data obtained from the reports of the twelve countries samples. The models used are four generalized production functions discussed recently in the literature. To make a choice among the alternative functional forms, specification error tests are performed. Having estimated the parameters of the production functions, their implications for the international trade patterns are considered.

DALE J. POIRIER, Ph.D. Wisconsin (Madison) 1973. Applications of spline functions in economics.

CHARLES S. PORTWOOD III, Ph.D. California (Berkeley) 1972. Statistics and their application to social sciences research.

BALDEV RAJ, Ph.D. Western Ontario 1973. The finite sample properties of several estimators of the linear regression models with random coefficients.

The random coefficients regression models are considered appropriate in situations where relevant variables cannot be explicitly included in the regression either because they cannot be measured or other considerations force their omission. This thesis discusses several economic applications of such models. Then, we undertake a Monte Carlo study of small sample and iterative properties of several estimators. Further, we propose new estimators including one which gives guaranteed positive estimates. Several other theoretical extensions are developed.

GOURANGA U. L. RAO, Ph.D. Western Ontario 1973. A Monte Carlo study of small sample properties of selected structural estimators.

The study reports the results of a series of Monte Carlo experiments conducted in order to throw some light on the small sample properties of certain structural estimators. In particular, attention is focussed on the effect produced on the small sample properties of estimators due to the presence of identities and lagged endogenous variables in models.

SUZANNE E. REID, Ph.D. Duke 1973. Corporate simulation: A theoretical approach.

STEVEN C. REIMER, Ph.D. Missouri 1972. Principal components and instrumental variables.

ARTHUR G. REITSCH, Ph.D. Oregon 1973. Statistical tests for detecting the presence of clusters in multivariate data.

HENRY G. RENNIE, Ph.D. Ohio State 1973. Aggregation theory, investment behavior, and rational lag functions.

Three types of measurement error caused by aggregation of investment functions utilizing the rational distributed lag function are presented: Coefficient estimates; lag structures and average lags; estimates of the residual variance. Twenty-seven corporations in six industries for the years 1951–68 were used for each of five investment theories. Aggregation bias at the industry versus firm level is very significant with respect to lag structure and average lag. Bias can also reverse conclusions concerning the relative performance of competiting theories.

MICHEL A. RICHONNIER, Ph.D. California (San Diego) 1972. Experimental design in econometrics: Some extensions.

The context is optimum design for regression analysis. A unifying interpretaion of conventional design criteria is given in terms of concentration ellipsoids. A sufficient condition is given for the optimal number of observations at a design point to be zero. Ordering constraints to be added to the constraint set in a time-series experiment framework are given. The classical orthogonality theorem is extended to time-series experiments, and numerical examples are provided.

KATTAMURI S. SARMA, Ph.D. Pennsylvania 1972. Comparative performance of input-output models with alternative production functions.

VERNON H. SAVAGE, Ph.D. Texas (Austin) 1972. The implications of national defense shifts to a small area: The San Antonio (Texas) case.

Shifting national defense priorities have implications not only to the national economy, but more especially to the regions and industries which have become specialized in this type of activity. This study chooses the San Antonio region and by the use of a Leontief static input-output model, analyzes the implications of such a shift to the region. The analysis is concerned with defense changes and its implications for income, output, employment, and the provision of public goods in the region.

GRAHAM C. SCOTT, Ph.D. Duke 1972. Industrial production and investment in a dynamic, multiregional, interindustry model of the United States.

TERRY G. SEAKS, Ph.D. Duke 1972. An econometric model of the North Pole, 1952–65.

JUDITH E. SELVIDGE, D.B.A. Harvard 1972. Assigning probabilities to rare events.

People's behavior when dealing with the uncertainty surrounding rare events is investigated in order to develop a good procedure for eliciting assessments of the subjective probability of occurrence of such events. Relevant current practices in two settings—specialty insurance underwriting and safety analysis for nuclear power plants—are described and evaluated; results of several experiments in assessing small probabilities are reported; and finally a three-step procedure is recommended for assigning a numerical value to express the uncertainty of rare events.

PHISIT SETTHAWONG, Ph.D. Michigan State 1973. An econometric analysis for Engel curves: Based on M.S.U. Consumer Panel data.

Using M.S.U. Consumer Panel data of 1958, thirteen cross-sectional studies on Engel curves were set out for five composite foods. Income elasticities were estimated based on three alternative mathematical forms of the Engel curves. Cross-sectional and time-series data were pooled. The modified Engel curves were formulated for estimating both income and price elasticities. Some preliminary evidence was presented on the approximate determination of utility functions by means of Engel curves.

M. LYNN SPRUILL, Ph.D. Michigan 1972. Secondary criteria for use with minimum bias estimation of response relationships.

EDWARD VENTO, Ph.D. Texas A&M 1972. Income distribution in a token economy.

WILLIAM E. WECKER, Ph.D. Michigan 1973. Time-series prediction: Theory and practice.

JAMES W. WETZLER, Ph.D. Harvard 1973. Studies on the American distribution of wealth.

This thesis consists of three studies: a survey of the data on the stock of personal wealth in the United States, its size distribution, and time trends in that distribution; measurement of the effective rates of the federal estate and capital gains taxes and the effects of tax loopholes on the rate of return received by the wealthy; and a cross-section study of the wealth-effect on savings using the Survey of Changes in Family Finances.

LAWRENCE C. WOLKEN, Ph.D. Texas A&M 1972. A dynamic price, production, and investment model of a monopoly firm.

Since a static model can only indicate the direction of change of a dynamic system, a dynamic model is developed to trace the firm's optimal path through time. To include the asset variables of the firm in a more direct way, investment is included as one of the control variables, determining the firm's optimal acquisition of capacity over time. A capacity constraint is included, which may restrain the monopolist from taking full advantage of his position.

Monetary and Fiscal Theory, Policy, and Institutions

ABDELRAHMAN T. ABURACHIS, Ph.D. Pittsburgh 1972. Monetary policy, high employment, and external finance.

This paper argues that in order for a central bank target to qualify as the object of central bank control it must meet two specific criteria: the target selected must have a stable and reliable relationship to expenditures; and it must have a stable and reliable relationship to the monetary base. In an aggregate investment equation and in four disaggregated investment equations—two for the business sector and two for the household sector—both the interest rate and the money stock failed to meet the criteria.

DAVID L. ANDERSON, Ph.D. Boston College 1973. A theoretical and empirical analysis of the federal budget process.

Using organization theory and adaptive modeling techniques, a new approach to public budgeting theory is developed. To explain the distribution of funds among defense, human services, physical development, and other budget categories, a simultaneous equation model is constructed and estimated for the postwar period. Structural and inertial forces within budgeting and economic conditions were the most significant explanatory variables; revenues and social factors the least. Decreasing intra-budget funding competition and declining administrative controls over budgeting are found to most hinder effective budget operation.

PANAYOTIS A. APOSTOLIDIS, Ph.D. Arkansas 1973. An investigation of selected operating ratios with emphasis on size of member banks of the Eleventh Federal Reserve District for the years 1960–1969.

Selected ratios—particularly the ratio of earnings to assets—were tested for bank profitability through regression analysis. Priorities in the allocation of resources were identified and marketing policies suggested. Problems of bank performance and scale economies were explored. The findings were compared with similar data from other districts and profit maximization was inferred to be a secondary objective after sales. The study however concluded that profitable coexistence of small and large banks is feasible.

PETER M. ASHTON, Ph.D. Colorado State 1972. Budget allocation in the public sector: A systems analysis of the Colorado Division of Wildlife.

Public finance is an uncomfortable arena in which important decisions tend to be made subjectively without the benefit of systematic economic analysis. A combined *PERT/PPB* cost-effective management system is developed and suggested as a technique for complementing traditional approaches to public budget allocation. The computerized system is evaluated to assess its potential for integrating various critical management functions into a comprehensive decision tool. It is concluded that systems methodology may

significantly enhance public resource allocation decisions.

HUSEYIN S. ATESOGLU, Ph.D. Pittsburgh 1972. Relative stability of monetary velocity and the investment multiplier: Turkey 1952–1967.

LEONARDO J. A. AUERNHEIMER, Ph.D. Chicago 1973. Essays in the theory of inflation.

These are four separate essays on inflation, the first three dealing with aspects of the theory of revenues from the creation of money: the revenue maximizing rate, the welfare costs of inflationary finance, and the stability properties of models where revenue is the exogenous variable. In the fourth essay a model of monetary adjustment is presented which allows for a lagged response of the rate of inflation to changes in the rate of monetary expansion.

EDGARDO BARANDIARAN, Ph.D. Minnesota 1973. The control of money and bank credit in Argentina.

A model of the Argentine monetary sector is developed. It consists of fifteen equations, ten of which explain the stocks of currency, demand, savings and time deposits, legal and excess reserves, ordinary and selective loans, and the interest rates on time deposits and ordinary loans. I present estimations of the structural equations using quarterly data for 1960I–1970IV. The estimated reduced form is then used to analyze the supply of money and bank credit and to evaluate policy instruments. Finally, the implications for the implementation of monetary policy are considered.

THOMAS L. BERTONE, D.P.A. George Washington 1971. Legislative control of executive expenditures in Maryland state government.

The study concludes that the General Assembly of Maryland exercised little control over executive operating expenditures through the budgetary system. The legislature chose not to become deeply involved in budgetary control because such control involves reductions of public services and possible voter retaliation. Broad control over expenditures was obtained, however, by allocating new tax revenues among expenditure categories through the device of funding formulas and special funds.

J. LLOYD BLACKWELL III, Ph.D. Georgia State 1973. A theory of bank structure with applications to problems of differential bank structures, bank pricing policies, bank cost, and bank management.

Models of systems of banks of various structures show that structural changes have welfare effects. The models are also used to compare costs of branch and unit banking, to evaluate branch bank pricing policies, and to develop a model of the optimal branch bank.

MICHAEL D. BORDO, Ph.D. Chicago 1972. The effects of the sources of change in the money supply on the level of economic activity: An historical essay.

The approach of the thesis is to compare different periods in *U.S.* monetary history over the time span 1834–1914 which exhibited different sources of monetary change to see whether the source of monetary change significantly affected the relationship between money and income between these periods as well as within them. In the majority of cases examined, the income effects of the sources of monetary change were found to be insignificant.

JOHN H BOWMAN, Ph.D. Ohio State 1973. Cost and benefit spillouts as factors affecting local taxation for public schools.

The dissertation analyzes factors affecting locally raised school taxes per pupil using linear regression analysis for West Virginia school districts. Ability to levy taxes for local use while exporting part of the burden (generally by taxing business property) was found to have a significant, positive effect on locally raised taxes. Intergovernmental aid extended without local matching or maintenance of effort was found to decrease local taxes; aid imposing such requirements was found to be insignificant.

ROBERT T. BRAY, Ph.D. California (Los Angeles) 1972. Church and welfare property tax-exemption: A study of Roman Catholic Church parish property in Los Angeles County, 1962–1968.

The study presents a model of the multiproduct church-firm based primarily on a Roman Catholic Church parish. Then, using the tax and assessment data of Los Angeles County, the study presents data for the measurable costs and benefits of the tax exempt status of Roman Catholic Church parish property in the county. And, the validity of church property assessments in the county is investigated. The study also includes a discussion of the immeasurable costs and benefits of church property tax exemption.

FREDERICK S. BREIMYER, Ph.D. Northwestern 1972. The money stock and the impact of high-powered money: An aggregated and regional investigation from 1879–1897.

The development of monetary institutions and relationships governing monetary movements were examined for the United States from 1879–1897. It was found that high-powered money explains less variation in money than explained by gold flows. Similar findings occurred using regional deposit breakdowns for national banks. The net deposit definition requiring reserves was discovered for each year, with the determination made that the official net deposit and required reserve data were incorrectly calculated and biased downward.

WYNN V. BUSSMANN, Ph.D. Wisconsin (Madison) 1972. Estimation of household corporate stock portfolios and a model of rate of return from a sample of Wisconsin income tax returns (1946–1964).

HARRY F. CAMPBELL, Ph.D. Queen's 1973. A benefit-cost rule for an additional public project in Canada.

ALEXANDER CASSUTO, Ph.D. California (Los Angeles) 1973. The stability of velocity and the effectiveness of monetary policy in developed and developing countries.

CHARLES D. CATHCART, Ph.D. Virginia 1973. Essays in monetary dynamics.

Three essays present new results on: The time path of the rate of monetary expansion and the stability of the monetary system in hyperinflation when the revenue from inflation is constrained; the excess burden and efficiency of inflationary finance when transitional dynamic effects and a positive growth rate of real income are introduced; and the stability of the monetary system when the rate of monetary expansion is fixed at a low level.

CLAUDIO CONTADOR, Ph.D. Chicago 1973. Money, inflation and the stock market: The Brazilian case.

GEOFFREY R. CONWAY, D.B.A. Harvard 1973. The supply of, and demand for, Canadian equities.

This study provides new statistical information on the market for Canadian stocks—size, ownership, new issues, future demands, etc. Some traditional views, i.e., that Canadians are conservative investors, are shown to be inaccurate. A major foreign investment factor illustrated is that almost 80 percent of the largest Canadian private companies are foreign controlled. The major conclusion is that Canadian institutional demand for stocks will exceed the Canadian supply unless many private companies go public.

TIMOTHY Q. COOK, Ph.D. Purdue 1973. The structure of long-term interest rates.

GILBERT L. COURSE, Ph.D. Purdue 1972. An investigation of the theory of money.

JAMES R. CROTTY, Ph.D. Carnegie-Mellon 1973. The objective function of the state: A study of the political economy of monetary and fiscal policy.

ADROALDO M. DA SILVA, Ph.D. Chicago 1972. Inflation and the demand for money: A four country model.

ROBERT T. DEACON, Ph.D. Washington 1972. The demand for services of local governments: Theory and evidence.

JAMES W. DEAN, Ph.D. Harvard 1973. Aspects of instrument/target links in Canadian monetary policy.

This dissertation examines certain links between instruments and targets of Canadian monetary policy. Reserves-to-money-supply links are analyzed in a money-multiplier context, instruments-to-reserves links are approached via estimates of the effectiveness of defensive policy, and feedbacks of targets to instruments are treated in a reaction-function context. Finally, the link between the secondary reserves instrument and its targets is analyzed using a model in which banks's utility depends upon income and liquidity.

DONALD M. DEPAMPHILIS, Ph.D. Harvard 1973. A microeconomic econometric analysis of the short-term commercial bank adjustment process.

The principal intent of this thesis is to construct a microeconomic model approximating commercial bank adjustment behavior in a period as short as a week. A set of behavioral relationships describing such adjustments is derived and estimated for a sample of seven large commercial banks. The model focuses on the activities of the money position manager in selecting the optimal "adjustment" portfolio. A specific emphasis is placed on the role of nondeposits sources of funds in this process.

J. KURT DEW, Ph.D. Texas A&M 1972. Generalized utility and cardinality price theoretic models of costs of trade.

LARRY L. DILDINE, Ph.D. Michigan 1972. The relation of local public service benefits to property values: Evidence from referenda.

WALTER DOLDE, Ph.D. Yale 1973. Capital markets and the relevant horizon for consumption planning.

STEPHEN M. DUCKWORTH, D.B.A. Harvard 1973. Post-CD liquidity management: A study of New England regional commercial banks: 1960–1972.

The dissertation investigates the effects of liability management on liquidity management practices of selected regional banks. Both determinants and financing of secular cyclical and short-term liquidity needs are analyzed and explained through statistical and interview data. The 1972 policies for discretionary bank assets and liabilities are developed with special attention to the factors effecting levels of temporary investments and the combined CD/net Federal Funds position.

DAVID B. EASTWOOD, Ph.D. Tufts 1972. Consumer credit and consumer durable expenditure.

MOHAMED M. EL-SHESHAI, Ph.D. Indiana 1973. Chance-constrained model for liquidity management in commercial banks.

This thesis studies factors affecting a bank's liquidity position. It describes how a commercial banker may act as a decision maker in a world of uncertainty. A key hypothesis is that the decision maker maximizes expected return subject to constraints dictated by a "tolerable" level of risk. The study develops a model designed to improve efficiency in managing the bank's liquid assets, compared to the usual "rule-of-thumb" one encounters. Efficiency is judged on the basis of cost and ability to meet Federal Reserve requirements.

DAWN E. ELVIS, Ph.D. Michigan 1972. The monetary sector of Jamaica.

DAVID ERICKSON, Ph.D. Florida State 1972. Analysis of the pricing and profitability of put and call options.

The study investigates the economic nature of the put and call option market, the pricing of options, and the profitability of alternative investment strategies. It was found using an option data set of 7416 actual transactions including both "bot" and "sold" premiums that option price can be explained by a log-linear function of duration, volatility, and price. Purchasing straddle options was found a viable strategy which can be expected to generate superior returns.

WILLIAM H. FOELLER, Ph.D. Iowa State 1972. A method for evaluating the impact and incidence of state and local taxes with applications to incidence and educational grant-in-aid programs in Iowa.

This dissertation uses the concept of legislative intent to assign the impact of state and local taxes of a state's residents and nonresidents. Then by various theoretically supported shifting assumptions, the incidence of state and local taxes is determined. An application of the procedure yields estimates of tax burdens on Iowans and effective rate patterns among income groups. Further application of the study method yields differential tax incidence of various state educational grant-in-aid programs.

BERNARD H. FRERICHS, Ph.D. Washington State 1973. A proposed public good pricing system for metropolitan areas.

This thesis develops a system of user charges for urban public services to make the property tax reflect the demand for public services. The goal of this tax, which is generated by a multi-dimensional tax base, is economic efficiency. Multiple regression analysis is used to formulate the relationship between public spending and characteristic variables. Data derived from municipalities within the Seattle *SMSA* are used to test the feasibility of constructing the relationships. This system of taxation appears to be feasible.

CARL M. GAMBS, Ph.D. Yale 1972. The economics of an automated payments system.

JAMES F. GATTI, Ph.D. Cornell 1972. Determinants of the percentage rate of growth of the United Kingdom money supply: 1950–1968.

RICHARD F. GLEISNER, Ph.D. Georgetown 1972. Short-run estimations of changes in the money multiplier and the money stock, 1957–1970.

First differences in the money supply are subdivided into the contributions due to changes in the monetary base and changes in the money multiplier. First differences in the money multiplier, in turn, are subdivided into the contributions of its determinants. Changes in the determinants are then estimated by least squares regression analysis. The R^2 and standard error of estimate of the estimations of changes in the money stock are significantly improved over estimations based on the assumption that the money multiplier retains its value of the previous quarter.

ESEN Z. GURTUNCA, Ph.D. Purdue 1973. A financial growth model.

In this thesis a Keynes-Wicksell monetary growth model with disequilibrium in security and commodity markets is constructed. The money market is not explicitly considered, but it is explained by reference to Walras' Law. After having constructed the model, neutrality of money and the effect of a stabilization policy on balanced growth equilibrium are examined.

JOHN P. HANSEN, Ph.D. Rice 1973. Should tax rates really be considered endogenous?

WILLIAM B. HARRISON, Ph.D. Maryland 1972. Institutional and cash flow variability effects on commercial bank spot accounts.

This thesis examines certain liquid assets and borrowing ('spot") accounts of 350 Fifth District banks. Moreover the relationships between these accounts and the particular sources of deposit and loan variability are studied. The institutional characteristics of banks serve as proxies for nonmeasurable cost differences from bank to bank, and these, too, are found to affect the relative levels of spot accounts. Discriminant analysis helps identify characteristics which distinguish borrowing from nonborrowing banks.

ARLINE A. HOEL, Ph.D. California (Los Angeles) 1973. The effect of reserve requirement changes on bank wealth 1913 to 1960.

Under certain conditions economic theory implies a negative relation between reserve requirement changes and bank equity changes. Bank stock prices, used as a proxy for equity, were collected for all reserve requirement changes between 1913 and 1960. The data were subject to the Chi-Square sign test, the t-test of means, and linear multiple regression analysis. The test results do not provide unambiguous evidence to support or reject the implied negative relation.

W. SLATER HOLLIS, Ph.D. Mississippi 1972. The economic costs of alcoholic beverages to governments and taxpayers: A study in public finance.

This interdisciplinary study hypothesized that the economic costs of alcoholic beverages to state and local governments are greater than the economic revenues received. Subordinate hypotheses were that alcohol is "the" or "a" primary cause of crime, accidents, disease, divorce, underemployment, and pollution and that they involve economic costs to governments. It was concluded upon testing that the hypotheses were valid and that the costs to governments are greater than the revenues by four to one.

PETER W. HOWITT, Ph.D. Northwestern 1973. Studies in the theory of monetary dynamics.

Three studies in disequilibrium monetary dynamics. Walras' tâtonnement theory is criticized as a conceptual framework for analyzing monetary price dynam-

ics. The stability of the long-run quantity theory is examined using a shopkeeper system that can serve as a general non-Walrasian framework for monetary dynamics. Keynesian short-run behavior is shown to occur out of equilibrium even if the long-run quantity theory is valid. This approach provides a nonmonetarist explanation of the observed correlation between money and income.

DANNIS J. JACOBE, Ph.D. Virginia Polytechnic Institute 1973. The National Dividend Plan: A public choice analysis.

A proposal called the National Dividend Plan has received considerable attention. The plan involves a proposed constitutional amendment which would limit the corporate income tax rate; make dividends nontaxable; and redistribute corporate income revenue to persons voting in the last preceding national election on a per capita basis. This study represents an investigation into the implications of the *NDP* by considering each of its most significant provisions, thus aiding the reader in evaluating the plan and answering for himself the question of its overall merits.

KAREN H. JOHNSON, Ph.D Massachusetts Institute of Technology 1973. Essays in monetary theory and policy.

RAYMOND M. JOHNSON, Ph.D. Oklahoma State 1973. The empirical question of money illusion in the United States: Its implications for a Patinkin type model.

The present study considers the implications which the presence of money illusion has for Patinkin's model, and estimates the degree of money illusion present in the economy. This involves the specification and estimation of a consumption function which uses the Kane-Klevorick price parameterization technique to estimate the degree of money illusion. The model is based on Patinkin's specification and includes permanent income, the interest rate, and real balances as independent variables.

JOHN F. JOHNSTON, Ph.D. Duke 1972. Toward a positive theory of redistributional public expenditures.

DAVID H. JONES, Ph.D. Texas (Austin) 1972. The transmission of the effects of an open market operation.

Ratios of their "quick" funds net to their total deposits-net—credit tightness ratios—were calculated for the weekly reporting banks in each Federal Reserve District and for those in New York City for the period July 1966 through December 1972. The credit tightness ratios of the weekly reporting banks in each Federal Reserve district is then expressed as some function of the credit tightness ratio of the N.Y.C. weekly reporting banks. Using the polynomial distributed lag model, final estimating equations for the credit tightness ratios of the twelve Federal Reserve Districts were obtained.

MARTIN E. JUDD, JR., Ph.D. Oklahoma State 1973. The demand for money by state and local governments.

In this study, widely accepted aggregate demand for money hypotheses are tested for the state and local government sector, the states of Washington and Wisconsin, and Northampton County, Pennsylvania. The periods of the study are: state and local government sector, 1957–68; state of Washington, 1957–68; state of Wisconsin, 1960–66; and Northampton County, 1964–68. The testable hypotheses are derived from the Keynesian motives approach to the demand for money.

HERBERT M. KAUFMAN, Ph.D. Pennsylvania State 1972. Price expectations and the demand for money: The American experience of creeping inflation, 1967–1970.

SAM R. KEELEY, Ph.D. Oklahoma State 1972. The existence of a long-run reaction function of the monetary authorities.

Implicit in the concept of a reaction function is the fact that it must apply on a temporally consistent basis. Since stability per se has received essentially superficial treatment, it was the purpose of this study to investigate whether the evidence supported the existence of a stable reaction function of the monetary authorities for the period 1951III to 1969IV. The stability tests employed were moving regression analysis to which confidence intervals were applied, the Chow test, and the generalized dummy variable test. Temporally stable reactions to employment and price stability objectives were found.

JAMES M. KENNEY, Ph.D. Stanford 1972. Credit availability and consumer investment in durable goods: The case of automobiles.

An aggregate structural model of the automobile loan market is formulated and tested (using quarterly time-series data for 1957–70) in order to assess the quantitative impact of changes in monetary policy on automobile expenditure. The lagged adjustment of the automobile loan rate is posited and is substantiated by the data. The resultant need for nonprice rationing in the automobile credit market is found to magnify the short-run impact of tight monetary conditions.

CHANDRA P. KHETAN, Ph.D. McMaster 1973. Econometric model of the Indian monetary sector.

A quarterly econometric model of the monetary sector of India is constructed. The model estimates using quarterly time-series for national income and its components are developed. Eight behavioral equations are estimated for the demand and supply of six principal financial assets. Seasonal variations in some monetary aggregates are dependent on seasonal variations in agricultural income and output. The price level appears sensitive to changes in the high-powered money supply.

DONALD W. KIEFER, Ph.D. Purdue 1972. Economies of scale in the provision of urban governmental services: An examination of city-county consolidations.

This study develops and illustrates a technique for examining governmental reorganizations to determine whether scale economies are achieved. The technique is illustrated by application to two public services in two city-county consolidations. The public services analyzed are government administration and primary and secondary education; the consolidations are in Virginia Beach, Virginia, and Nashville, Tennessee.

IN KIE KIM, Ph.D. Maryland 1972. The sources and changes in the stock of money in the case of Korea 1954 to 1969.

GREGORY C. KROHM, Ph.D. Virginia Polytechnic Institute 1973. An economic analysis of municipal annexation policy: Approached from the theory of fiscal clubs.

Annexation is one of the major means by which the service areas for local public goods are altered. This dissertation examines the variation in state statutes dealing with annexation. It attempts to interpret the legal criteria for annexation in the light of academic theory, especially recent theories dealing with the optimal organization of local "fiscal clubs." Although all states are surveyed, special emphasis is placed upon the particularly interesting case law which has evolved in Virginia.

FINN E. KYDLAND, Ph.D. Carnegie-Mellon 1973. Decentralized macroeconomic planning.

JULIAN E. LAGRAND, Ph.D. Pennsylvania 1972. An investigation of the utility function implicity in government taxation and expenditure decisions.

DANIEL J. LARKINS, Ph.D. Georgetown 1973. Defensive and dynamic lags in open market operations.

A reduced form model is used to estimate the lags between *OMO* and changes in the money stock during the 1960's. The results suggest that, contrary to the findings of other investigators, the lags are not so long as to vitiate discretionary monetary policy.

JOHN E. MCCAIN, Ph.D. Oklahoma State 1973. Expenditure response of local governments to external grants-in-aid.

This study examined the question of how local government expenditure levels on major functions changed as a consequence of receiving external grants-in-aid. An answer was sought as to whether aid recipients substitute outside funds for local funds, or whether the aid acts as a stimulant to expand local spending from locally raised resources. Hypothetical responses were tested empirically by the use of statistical linear regression analysis to estimate the actual expenditure response, and the extent to which this response conformed or deviated from the a priori theoretical model.

MARVIN MCCLAY, Ph.D. Oregon 1973. Comparative investment performance of bank pooled trust accounts and mutual funds.

J. HUSTON MCCULLOCH, Ph.D. Chicago 1973. An estimate of the liquidity premium.

The liquidity premium is estimated using the assumption of unbiased forecasting. Although the expectations hypothesis is far from applicable for forward interest rates of short duration, it cannot be shown to be wrong for forward rates of long duration. When a form that increases at a decreasing rate is imposed on the liquidity premium as a function of maturity, the premium becomes virtually negligible for forward loans of more than a few years duration.

MELVILLE L. MCMILLAN, Ph.D. Cornell 1973. Jurisdictions, grants, and public good supply in a fiscal federalism.

EDWARD MALCA, Ph.D. City University of New York 1973. Performance and characteristics of bank-administered commingled equity funds for employee benefit plans, 1962–1970.

This study investigates the performance and characteristics of thirty-seven commingled pension funds during the period 1962 through 1970. Employing methodology similar to the recent SEC study, it was found that, adjusted for risk (the mean *beta* was .96) average portfolio return for these funds was a 1.6 percent per annum worse than pure random selection would have produced. Of the thirty-seven funds, thirty did worse than totally "unmanaged" portfolios. It was also found that portfolio turnover, bank size, fund size and size growth rate were irrelevant to performance. Also there was no consistency in year-to-year performance by any of the thirty-seven institutions.

CLAYTON G. MAMMEL, Ph.D. Kentucky 1973. The short-term fluctuations of regional housing and mortgage markets.

This dissertation is concerned with the problem of explaining regional variations in the short-housing cycle. The focus is on the financial aspects of these fluctuations as they are manifested in regions.

JAMES B. MARSH, Ph.D. Chicago 1972. A theory and estimation of gold supply: The case of South Africa, 1956–1966.

The study integrates the theories of multiple outputs, natural resource exhaustion, and gold supply into a general theoretical model of mining production. The model is then tested against data from the South African gold-uranium industry, and short-run gold supply elasticities are computed.

GEORGE R. MEADOWS, Ph.D. Washington (St. Louis) 1972. Residential property values and local public budgets: An empirical study of the capitalization of local property tax and expenditure differentials.

This study investigates the capitalization of inter-

community differentials in property taxes and local public services into the value of residential dwellings. A household location model illustrates the expected theoretical relationship. The empirical model proceeds from the concept of housing as a composite commodity defined over dwelling and community characteristics. The empirical results are generally supportive of the capitalization hypothesis. The results indicate that certain property tax reforms may result in important changes in property values.

LAWRENCE J. MURPHY, Ph.D. McMaster 1973. An analysis of the demand for Government of Canada marketable debt.

This thesis provides a systematic analysis of the portfolio behavior of the principal holders of Government of Canada securities. Nongovernment participants in the market for these securities are chartered banks, nonbank financial institutions and nonfinancial corporations. A theoretical model of portfolio behavior is specified. Changes in the portfolio structure of these institutions over time are examined. Econometric techniques are used to evaluate the principal determinants of the demand for Government of Canada securities by each institution.

WILFRIED R. MUTH, Ph.D. Southern Methodist 1973. An econometric model to evaluate monetary and fiscal policies in Germany.

This dissertation presents an econometric model for the evaluation of monetary and fiscal policies in West Germany. For the estimation, quarterly data are used covering the period 1957–70.

FOREST E. MYERS, Ph.D. Kansas State 1972. Differential industry impact of monetary and fiscal policies: An interindustry model.

FERNANDO E. NARANJO, Ph.D. Pennsylvania 1973. A macroeconometric model of fiscal policy for Costa Rica.

JOHN A. NERI, Ph.D. Maryland 1973. Income expectations and the accumulation of real cash balances.

Short- and long-run income expectational elements are combined and applied to money demand. Expected income hypothesis is a generalization of adaptive expectation scheme in that adaptive, regressive, and extrapolative forces are combined. The objective is to determine whether holdings of cash balances are adjusted to expected short- or long-run income position. Distributed lags on current and past values of income are estimated via polynomial interpolation. I conclude that holdings of real balances are adjusted to short-run rather than long-run income position.

DOUGLAS A. NETTLETON, JR., Ph.D. Oklahoma State 1972. The impact of deposit variability on average labor cost in commercial banking.

This dissertation seeks to ascertain whether deposit variability is a determinant of average labor cost in commercial banking. Cost and deposit level data from the Federal Reserve reports of a sample of forty banks were used. So as to distinguish the impact of deposit variability on average labor cost from the impact of bank size on average labor cost, banks in the sample are divided into five size categories. Cost functions are then estimated. Average labor cost was positively related to deposit variability.

ELDON J. NOSARI, Ph.D. Kentucky 1972. National bank entry.

This study argues that fixed entry standards are a more desirable method of controlling rates of entry into banking. If fixed entry standards are to be utilized, knowledge of the determinants of desired entry into banking is required. This study is an initial attempt to investigate such determinants through the development of a national bank entry function. The main conclusion is that the expected rate of return in banking derived from historical data is statistically significant in explaining the variability of desired national bank entry.

LOUIS E. NOYD, Ph.D. Oregon 1973. An empirical test of government's demand for money: The local government case.

TOM OBERHOFER, Ph.D. Rutgers 1973. The redistributive effect of the federal income tax: A time-series and cross-section study.

The redistributive effect of major federal personal income tax components is estimated from time-series and cross-section samples. The Gini coefficient measures income concentration. Exemptions, combined exemptions and deductions and tax rates contribute to the progressivity of the tax while the inclusion of deductions decreases the progressivity of the tax. The redistributive effect of tax components varies as sample mean income varies.

BRUNO A. OUDET, Ph.D. Indiana 1972. An examination of returns on financial assets during periods of inflation.

Hypotheses on the variation of returns of financial assets in periods of inflation are formulated from the existing theories and tested empirically. The justifications of the proposition that stocks are a good hedge in periods of inflation are reexamined, and it is shown that various time patterns of variations of stock prices are in fact possible. The analysis reveals that, whereas in the long run stocks do provide a perfect hedge against inflation, falling stock prices can be quite consistent with the theory in the short run.

SEUNG OH PARK, Ph.D. Kentucky 1972. The tax exporting adjustment in interstate comparison of tax burdens.

Business and personal shares of state-local tax revenue are estimated for fifty-one states for 1967. Because business tax exporting can be influenced, but importing cannot, states with lesser emphasis on busi-

ness taxes and/or lower business values per capita have family tax burdens that are higher than is suggested by the taxes-per-capita measure.

JOSEPH E. PLUTA, Ph.D. Texas (Austin) 1972. Growth and patterns in U.S. government expenditures, 1956–1970.

This study analyzes the growth and changing patterns in *U.S.* public expenditures between 1956–70. It updates past budget studies and combines the scattered literature of the past fifteen years on aspects of the public budget. The growth in outlays is examined to determine the relative shift in priorities to domestic areas. To the extent that relative changes in the budget have proceeded in the direction of education, income maintenance, housing, public health and have been the result of intense federal legislative action, this change in priorities is termed a Social Revolution.

ELLIOT PONCHICK, Ph.D. Southern California 1973. The effects of monetary and fiscal policy on the distribution of wealth in America.

This research is an inquiry into the wealth distributional effects of government policy that operate indirectly through interest rates and the price level. To find how wealth is distributed an individual's portfolio selection process is explored. This selection process is a function of the amount and kinds of information concerning market activities he possesses. It is shown that the larger the portfolio the greater the incentive to acquire information. Optimal purchasing times are earlier and returns greater, the larger the portfolio.

MARY E. RIEDER, Ph.D. Iowa State 1973. A simultaneous equation model to determine the rate of inflation.

This study concerns itself with the direct effect of changes in the money supply on wages and prices in the context of a simultaneous equation system. To do this an eight-equation quarterly macromodel of the United States was formulated and estimated from 1952 to 1969. The model was taken into its derived reduced form and the matrix of reduced form coefficients computed from which several observations about the economy were made.

EDMUND J. ROLLO, Ph.D. West Virginia 1972. The financing of highways in West Virginia with suggestions for reform.

JAYANTA ROY, Ph.D. California (Berkeley) 1972. A model highlighting fiscal and monetary policy effects in India 1950–1965.

FRANK S. RUSSEK, JR., Ph.D. Maryland 1972. The Tax Reform Act of 1969: A study of its relative impact on housing investment.

This study estimates the differential effect of various tax reforms on investment in housing and other durable assets. Micro-simulation models are used to calculate the tax-induced changes in the present value of apartment buildings, office buildings, and producers' equipment. Macro-simulation experiments are performed with a variant of the FRB-MIT econometric model to determine how different tax provisions alter investment in housing, producers' structures, and equipment when overall investment is held constant.

MICHAEL SARRIS, Ph.D. Wayne State 1972. An analysis of the findings for monetary and fiscal policy in reduced form macroeconomic models.

ROGER W. SCHMENNER, Ph.D. Yale 1973. City taxes and industry location.

JOHN B SHOVEN, Ph.D. Yale 1973. General equilibrium with taxes: Existence, computation, and a capital income taxation application.

WILLIAM G. SMILEY, Ph.D. Iowa 1973. The evolution and structure of the national banking system, 1870–1913.

The period of 1870 through 1913 was one of rapid economic development and industrial transformation in the history of the United Utates. The role of the national banking system in facilitating this development and transformation has long been the subject of debate. It was often suggested that the national banks were relatively ineffective in transferring financial capital from the more industrialized regions—the New England, Middle Atlantic, and later, East North Central regions—to the more rapidly developing southern and western regions. The present study is concerned with developing a basis for more accurate evaluation.

SUNG WON SON, Ph.D. Pittsburgh 1972. Certificates of deposits in liability management.

The first two chapters are devoted to the discussion of the development of various money market instruments and their contributions to commercial bank liability management. The core of the dissertation is the third chapter which develops the theory of liability portfolio selection using the mean-variance approach to Tobin-Markowitz. Chapter four attempts to obtain empirical support for the theory developed earlier. Finally, the entire study is summarized in chapter five.

LARRY V. ST. LOUIS, Ph.D. Oregon 1972. Price expectations and the term structure of interest rates.

HOWARD K. STOKES, JR., Ph.D. Georgetown 1973. Portfolio theory: The estimation of indifference curves for government securities.

The dissertation attempts to estimate a risk return preference function in the Tobin-Markowitz tradition. Data for six maturity classifications and seven financial intermediaries were taken from the U.S. Treasury Survey of Ownership of Government Securities. A *CES* utility function was used in the estimation. The results indicate a stable, but yet concave, preference function. An extension is then presented to the analysis of the term structure of interest rates.

GERALD W. STONE, JR., Ph.D. Rice 1973. The fiscal

feasibility of land value taxation in urban metropolitan communities.

RAINER STUPER, Ph.D. Florida State 1973. An empirical analysis of the debate over rules versus discretion with special reference to the monetary management of the German Bundesbank from 1958 to 1970.

An attempt to evaluate performance of strategies propounded for monetary policy which use the money supply as indicator. Strategies considered are "fixed" rules, which confine the growth of the money stock to some constant rate; "flexible" rules, which employ formulas to establish required change in money stock and discretion, represented by actual responses of the monetary authority. The study compares their potential success in minimizing the gap between actual and desired state of the economy.

WAYNE K. TALLEY, Ph.D. Kentucky 1972. A model for distributing state aid to local school districts.

ROBERT D. TOLLEN, Ph.D. Texas (Austin) 1972. Bank asset management and the monetary policy lag.

The dissertation is an attempt to explain the behavior of the monetary policy lag through an investigation of the portfolio behavior of the banking system. The technique used is regression of the rate at which banks accommodate loans on the monetary lag in effect. This procedure requires generation of data reflecting the rate of change of loans, and extraction from this data-set of a behavioral variable for each observation over the business cycle. These behavioral variables represent the set of observations of loan accommodation which are regressed on the monetary lag.

YALCIN TUNCER, Ph.D. Pittsburgh 1972. Portfolio analysis with indirect utility.

This dissertation attempts to determine an optimal portfolio beyond the mean-variance analysis. The underlying rationale relates to the generalized risk aversion which depends upon functional forms of utility and existing moments of probability distributions. Using a specific utility function and the first four moments of an illustrative sample of common stocks, an empirical study is conducted. Given identical means and variances, the above aversion is found to imply a preference for positively skewed platykurtic portfolios.

TERRY L. TURNER, Ph.D. Carnegie-Mellon 1973. A theory of imperfect markets and of the demand for money.

THOMAS J. VALENTINE, Ph.D. Princeton 1972. An economic analysis of the Australian monetary sector.

This study describes a medium-sized quarterly econometric model of the Australian economy which was constructed with special emphasis on the monetary sector of the economy. Special attention is given to the behavior of the Australian equivalent of the U.S. commercial banks, the trading banks, and to the effect of this behavior on the real sector of the economy. The trading banks use the overdraft method of lending, and this factor is of central importance in the analysis. The final chapter of the study describes the complete model and presents equation estimates obtained by simultaneous equation techniques.

EDWARD E. VEAZEY, Ph.D. Michigan State 1973. Aggregation bias in the demand for money.

GEORGE M. VREDEVELD, Ph.D. Indiana 1973. Income redistributive effects of subsidizing public higher education in Indiana.

There has been a long tradition of subsidizing higher education in the United States. Yet, higher education subsidization policy suffers from a lack of serious economic review and analysis. The lack of analysis partly explains the situation in which educators agree that subsidizing education increases the quantity of education consumed but disagree about whether subsidizing education encourages a more equal distribution of income. This income-redistributive aspect of subsidizing higher education, which warrants serious study, is the focus of this dissertation.

DAVID R. WEINBERG, Ph.D. California (Berkeley) 1973. The effects of state sales taxation on prices, income, and employment.

BERNARD L. WEINSTEIN, Ph.D. Columbia 1973. The adequacy of the state tax base to support elementary and secondary education in 1980.

School enrollments and per pupil expenditures are projected by state to 1980 to determine the demands on the state fiscs. Market property values and personal income are projected by state to 1980 as measures of fiscal capacity. It is found that for thirty-seven of the fifty states, school costs expressed as a percentage of personal income should be lower in 1980 than in 1970. The case is made for full state financing of education.

JOHN A. WENNINGER, Ph.D. Washington (St. Louis) 1972. Political economy of monetary policy.

This research focuses on the limitations of conventionally defined monetary policy. Two types of problems complicate monetary policy with respect to the systematic attainment of the conventional objectives. These problems are structural constraints and the Federal Reserve's "support functions." A single model is incorporated to illustrate the possible implications of these "constraints" on the Federal Reserves behavior. This research results basically in a study of the Federal Reserves behavior from 1962 through 1971.

JOSEPH E. WHITBREAD, Ph.D. Syracuse 1973. A test of a total reserves based open market operations strategy for the Federal Reserve System, 1953–1969.

This is an empirical test of the feasibility of an open market strategy which employs total reserves as its near term target so as to control bank credit. The test was conducted over the years 1953–1969 using a monthly, non-linear model of the bank credit market patterned after the Brunner-Meltzer non-linear money supply hypothesis. It was found that gross national product was significantly influenced by the level of bank credit outstanding.

JOHN E. WHALLEY, Ph.D. Yale 1973. A numerical assessment of the April 1973 tax changes in the United Kingdom.

CHARLES E. ZECH, Ph.D. Notre Dame 1973. Regressivity and the property tax: Alleviation and tradeoffs.

This study is concerned with analyzing means for reducing the regressivity of the residential property tax. To this end, Minnesota state data are used to test two types of property tax relief programs: property exemptions, and the property tax credit. The property tax credit is shown to be more successful at alleviating regressivity at a reasonable cost to the state.

International Economics

JOHN M. ABBOTT, Ph.D. Tulane 1973. An investigation into the determinants of U.S. direct investment: 1950–68.

A simultaneous equation model of supply and demand for *U.S.* direct investment abroad is specified and estimated. The supply function includes the rate of return on domestic investment, the rate of return on foreign investment, and changes in the domestic flow of savings. The demand for direct investment is derived from a portfolio stock adjustment model. The model is applied to several countries. In general, changes in the level of *GNP* in the foreign country and changes in *U.S.* domestic savings are the dominant explanatory variables.

BIJAN B. AGHEVLI, Ph.D. Brown 1973. A model of the balance of payments and the money supply under the Gold Standard Regime: United States 1879–1914.

A theoretical open model is developed and tested econometrically to investigate the interaction between the real and monetary sectors. It is shown that contrary to the Cagan, Friedman, and Schwartz position, there were strong feedbacks from the real sector affecting the money supply through the balance of payments. The capital flows are shown to move procyclically (verifying Mundell's and Williamson's position), even though they were dominated by the anticyclical movements of the trade balance.

MALCOLM D. BALE, Ph.D. Wisconsin (Madison) 1973. Adjustment to freer trade: An analysis of the adjustment assistance provisions of the Trade Expansion Act of 1962.

HASSAN O. BALKHY, Ph.D. New Mexico 1973. International trade and income distribution: A 3x3 model.

A system is devised to rank commodities according to factor intensities when three factors are employed to produce three commodities. Some of the results rigorously analyzed in the 2x2 model are extended to the 3x3 model. The thesis employs the 3x3 model to analyze the cost of income redistribution when international trade tools are employed for that purpose.

BAROUCH BEN-ZION, Ph.D. Oregon 1973. Alternative concepts of export diversification: An application to the analysis of export growth.

TAPAN K. BISWAS, Ph.D. Rochester 1973. Nonshiftable capital and imported inputs in economic growth and international trade.

Economic growth in a trading economy has been discussed in the context of a nonshiftable capital structure. I have examined the significance of the myopic decision rule and have proved the stability of the long-run equilibrium when such a rule for investment allocation is adopted. Lastly, I have examined the role of imported inputs in a trading economy where capital is not shiftable.

ARYEH BLUMBERG, Ph.D. Chicago 1973. Eurodollars and the balance of payments: Some empirical evidence on two types of fractional Euro-dollar effect on the official settlements balance of the United States.

The thesis develops a quantitative framework for monetary approach to balance of payments. Demonstrates role of Euro-dollar reserve ratio by estimating fractional slopes of Official Settlements functions vis-à-vis Canada, Japan, eight European countries, using difference between Euro-dollar credit creation and Euro-dollar creation, termed conversions, as the independent variable. I demonstrate that in European case true Official Settlements balance is indeterminate within fractional range because of Euro-dollar deposits of monetary authorities.

ROBERT W. BOATLER, Ph.D. Cornell 1973. Trade theory predictions and the growth of Mexico's manufactured exports.

ROGER E. BOVE, Ph.D. Harvard 1973. Programming foreign aid with diminishing returns to investment.

This is a study of Chenery's two-gap model using a variable incremental capital-output ratio and a non-linear objective function. Evidence is presented to show that the usual assumption of a constant incremental capital output ratio is untenable. A capital accumulation function due to Robert Dorfman is introduced and explained. Finally non-linear programming the models for a 22-year plan are solved by Abadie's *GRG* method. Unlike its linear predecessors the model yields multiple-peaked capital flows but the three results due to Chenery and MacEwan stand.

I. BRYAN, Ph.D. Alberta 1972. Essays on transportation and trade.

THAI VAN CAN, Ph.D. Michigan State 1972. Capital flows and international adjustment.

This thesis uses a one-country model similar to Patinkin's as well as a two-country model to investigate the effectiveness of fiscal and monetary policy (consisting of changing outside and inside money) under the hypothesis that international capital flows influence aggregate demand by changing the level of real balances. Fiscal and monetary policy are generally found to be effective in each of the models.

FRANCISCO R. CASAS, Ph.D. Western Ontario 1973. Intermediate goods and the theory of international trade.

A survey of the recent trade literature reveals three major interpretations of the nature of intermediate goods: interindustry flows; pure intermediate products; and imported inputs. The thesis brings these interpretations closer to each other and provides some insights into the theory of intermediate goods in the context of international trade by investigating the general equilibrium properties of various two-sector models incorporating such goods.

DONALD M. CHAFFEE, JR., Ph.D. California (Davis) 1972. A contribution to customs union theory.

JOHN W. CHAMBERS, Ph.D. Claremont School 1972. Britain's balance of trade and the 1967 devaluation: A case study of the efficacy of devaluation in correcting a trade deficit.

The devaluation of the pound in November 1967 was accompanied by a number of other policy changes designed to reduce domestic demand (absorption), and hence contribute to an improvement in the balance of trade. This study is an attempt to isolate the impact of the devaluation, and to judge its effectiveness in improving Britain's balance of trade.

CHI-MING CHENG, Ph.D. Yale 1973. The determinants of international trade of manufactures: An empirical study.

ESHETU CHOLE, Ph.D. Syracuse 1973. Import substitution in practice: The case of the Ethiopian textile industry.

Import substitution has been the major strategy of industrialization in many underdeveloped countries. During the initial phase imports are curtailed (generally by a tariff wall) and production is geared toward satisfying domestic demand. When this is achieved there is need to move into the second phase—production of capital and intermediate goods, or production for export, or both. This paper attempts to assess various effects of import substitution in the Ethiopian textile industry.

YEI-CHOU BETTY CHU, Ph.D. Notre Dame 1973. Variable factor supplies and the pure theory of international trade.

The traditional fixed factor supplies assumption is abandoned. With the assumption of variable factor supplies and newly designed graphical analysis, various interesting points are found. Some findings are paradoxical in the light of ordinary economic theory. One of these is that output of a good responds perversely to its price. Another surprising contribution concerns specialization behavior in trade theory, namely, the country might go back to incomplete specialization after reaching complete specialization under certain conditions.

DAVID S. CLEAVER, Ph.D. Illinois (Urbana) 1972. A mathematical model of devaluation and relative price changes applied to Denmark in 1967–1968.

SCOTT F. CLOW, Ph.D. Illinois (Urbana) 1972. Trade and growth: A test of alternative theories.

FRANCIS J. COLELLA, Ph.D. Fordham 1973. An econometric study of United States-Canada short-term capital flows.

This dissertation measures the sensitivity of the short-term capital flow (between the United States and Canada, 1959–70) to the forces charged with its determination by the theory of short-term capital flows. These forces include interest rate differential, portfolios, money stocks, investment, prices, trade balance, and fiscal policy. Specification of the relationship between each variable and short-term capital flow is established by a review of the literature of theoretical and empirical studies.

RALPH K. COWAN, Ph.D. Michigan 1972. Effects of the United States-Canadian automotive agreement in Canada's manufacturing trade and price program.

WILLIAM P. CULBERTSON, JR., Ph.D. Texas (Austin) 1972. The burden of balance-of-payments adjustment.

This dissertation attempts to accomplish three goals. First, I survey the literature on the distribution of the international "burden" of balance-of-payments adjustment. Second, the relevant features of this literature are subjected to critical scrutiny, and the validity of the composite view of adjustment burdens is assessed. Finally, I find that the burden of international adjustment is always "shared" to some degree by the various nations involved. I conclude that the incidence has been largely visited upon the major surplus countries.

JAIME R. DAREMBLUM, Ph.D. Fletcher School 1972. Proposals for a general increase in the price of gold: An analysis.

GEORGE E. DRAKOS, Ph.D. Rochester 1973. Policy and the balance of payments.

The first part of this dissertation explores the effects on the balance of payments of the substitution of an equivalent value-added tax for the corporate income tax using a 2x2 and a 3x2 model of international trade for a small country. The second part uses an input-output model and investigates the price changes, following the tax change, and the resulting change in the balance of payments using Greek data.

ROBERT A. ELSON, Ph.D. Columbia 1973. Exchange rate policy and the performance of traditional exports in Argentina, 1946–1970.

This study shows the effects of changes in exchange rate policy on traditional exports in Argentina during the postwar period, before and after 1955. During the first phase, when traditional exports stagnated, exchange rate policy overvalued the Argentine peso vis-à-vis other currencies. However, during the second phase, when exchange rate adjustment was frequently used, traditional exports recovered. Theoretical and empirical results are presented in terms of a model of traded and nontraded goods.

NABIL C. M. FALTAS, Ph.D. California (Berkeley) 1972. Methodological and implementational issues in the design of international economic relations.

JERRY A. FEDELER, Ph.D. Iowa State 1972. An analysis of commodity aid and policies to eliminate its negative effects upon the commercial market.

Gross negative effects of foreign aid commodities are analyzed when aid displaces the recipient's production. An input-output model is used to show the distribution of negative effects among sectors of the Indian economy. Four policy alternatives to eliminate the losses in income arising from the negative effects are considered. One is a new application of a differentiated market. Monetary effects of concessional sales for the recipient's currency are shown to be an empirical question.

WARREN L. FISHER, Ph.D. Connecticut 1973. Processes in line, American agriculture, and the Leontief Paradox.

Following a thorough review of the literature of the Leontief Paradox, the Paradox is reexamined in light of Georgescu-Roegen's recent observation that parallel processes (such as agriculture) are overcapitalized relative to in-line processes. The upshot is that Leontief's estimates could have been biased by the existence of parallel-process industries in the United States. A method for estimating this bias is developed; data limitations prevented estimates.

ALLEN B. FRANKEL, Ph.D. Oregon 1973. A borrower-oriented model of U.S.-Canadian long-term fixed-interest capital flows.

JOHN H. GAILLIOT, Ph.D. Carnegie-Mellon 1973. Long-run determinants of the distribution of international monetary reserves.

DAVID H. GEDDES, D.B.A. George Washington 1972. U.S. direct investment overseas, 1968–1970: An analysis of corporate financial decision making as affected by the U.S. foreign direct investment program.

This dissertation establishes the optimum use of program allowables, the level of program constraint, and the minimum amount of long-term foreign borrowing use required to comply with the provisions of the Foreign Direct Investments Program for the years 1968–70 Computer modeling techniques are used, and individual company model results are statistically measured against actual company results.

KATHIE S. GILBERT, Ph.D. Louisiana State 1972. An evaluation of the association between Greece and the European community.

MANUEL GUITIAN, Ph.D. Chicago 1973. Devaluation, monetary policy, and the balance of payments.

A general equilibrium model shows how the government, by using aggregated demand policies, temporarily influences economic activity. In the long run, however, aggregate supply determines output and employment levels. International reserves are lost (gained) during the adjustment process due to policies which keep aggregate demand above (below) its long-run sustainable level. Such policies, if maintained, induce expectations of exchange rate changes. The self-fulfilling character of these expectations will force the government to devalue or revalue, thus neutralizing its previous demand policies.

JOHN J HAMPTON, D.B.A. George Washington 1971. Currency appraisal aspects of Euro-bond financing.

This study examines the factors which affect the costs of borrowing in different currencies for Euro-bond financing. It includes a background study of the Euro-bond market, a review of currency appraisal literature, a study of forecasting future exchange-rate adjustments, and a computer-based model for measuring the effective cost of Euro-bond financing.

RICHARD J. HERRING, Ph.D. Princeton 1973. International financial integration: Capital flows and interest rate relationships among six industrial nations.

Starting with the expected value maximization of a negative exponential utility function, equations for a two-country financial balance sheet are derived and the implications for capital flow and interest rate equations are deduced. Capital flow and interest rate equations are estimated for Canada, Germany, Italy, Japan, the United Kingdom, and the United States. Finally these empirical results are put together to construct an interdependent model of capital flows and interest rates.

MAXWELL W. HUDGINS, JR., Ph.D. Virginia 1973. Currency exchange rate fluctuations under a system of stabilization funds: The case of the pound-dollar rate, 1931–1938.

This study uses least squares regression analysis to investigate the fluctuations in the pound-dollar exchange rate from 1931 to 1938, emphasizing the intervention activities of the British Exchange Equalisation Account and the American Stabilization Fund. It is concluded that only the British Account had a significant effect on this rate. I also analyze whether or not competitive devaluations were pervasive in the 1930's and the implications of the Tripartite Currency and Gold Agreements.

LACY HUNT, Ph.D. Temple 1969. The Euro-dollar market capital flows, and the U.S. balance of payments: An econometric study.

ROBERT R. JOHNSON, Ph.D. Oregon 1973. Uncertainty in a general equilibrium model of international trade.

FRED R. KAEN, Ph.D. Michigan 1972. Euro-currency and national money market integration: An appraisal.

HARALD KNUDSEN, Ph.D. Oregon 1973. Expropriation of foreign private investments in Latin America.

ODIN K. KNUDSEN, Ph.D. Stanford 1972. A permanent income theory of export instability.

This study develops the concept of income instability as the dispersion of transitory income and utilizes the permanent income hypothesis of consumption to graft the study of export instability to the main body of economic theory. It derives a specific theory which incorporates a behavioral hypothesis from which to develop indices and empirical tests. The finding is that instability stimulates certain economic parameters in a direction predicted by the permanent income theory, a finding contrary to the a priori reasoning of extant literature on export instability.

RISHI KUMAR, Ph.D. Wayne State 1972. U.S. monetary and fiscal policies and the balance of payments since 1952: An evaluation.

GEORGE H. LAMSON, Ph.D. Northwestern 1970. Central banking in an open export economy: The monetary system of French-speaking West Africa, 1956–1967.

The goals of this dissertation were: to analyze a relatively exotic monetary union in which the central bank's major role was determining the allocation of bank credit through rationing at the rediscount window; and to better define optimum monetary policy for open, export economies. Its conclusions were that in such economies the money stock was better determined by a specie-flow-type mechanism than by discretionary counter-cyclical policies, and that "monetary independence" was limited to assuring that secular increases in the demand for money do not produce excessive official capital exports and that its counterpart savings are optimally allocated between competing domestic projects.

DANNY M. LEIPZIGER, Ph.D. Brown 1973. Long-term capital movements and economic policy: Canada (1953–61).

The dissertation examines the effects of foreign portfolio and direct investment on the Canadian economy under a regime of flexible exchange rates for the 1953–61 period. The thesis is further concerned with the respective roles of fiscal and monetary policy in the stabilization process, in cases of imperfectly mobile and perfectly mobile capital. A theoretical two-sector model is developed, based on five dynamic markets, proven stable and examined in equilibrium. The model is estimated by two-stage least squares.

LUIS LIBERMAN, Ph.D. Illinois (Urbana) 1972. Foreign trade and economic growth: The case of Costa Rica.

JOHANNES F. LIN, Ph.D. Cornell 1973. Economic policy in an open economy.

JENS R. LINDEMANN, Ph.D. Kentucky 1972. West German demand for foreign exchange reserves.

RACHEL MCCULLOCH, Ph.D. Chicago 1973. Import quotas and resource allocation.

The study compares quotas with tariffs as means of achieving national policy objectives. In some cases a quota is shown to entail a smaller welfare cost than a comparable tariff (where comparability is defined in terms of the policy objective underlying restriction). The relative costs depend on the policy objective, the structure of the market in the protected good, and the method of allocating the import licenses used to implement the quota.

MICHAEL S. MALONE, Ph.D. Kansas 1973. Tariff discrimination in a large country trade model: an application to customs union.

The study describes a three-country, two-commodity neoclassical model of international exchange in which one country can affect its terms of trade through the imposition of a tariff. The analysis of the model suggests that tariff optimization leads to discriminatory tariff rates in conjunction with customs cooperation.

JAMES L. MILLS, Ph.D. Oregon 1973. Analysis of the Mexican monetary system.

RAO S. MUSUNURU, Ph.D. Chicago 1973. Protection to fertilizer industry and its impact on Indian agriculture.

Effective rates of protection to the nitrogen fertilizer industry in India are estimated for the two periods 1961–65 and 1968–71. Production costs of such protection are computed using the effective rates. Consumption costs of protection are computed on the basis of estimated demand elasticities for fertilizer, and the net loss in agricultural production due to protection. These costs are shown to be significant, and

this protection may prove to be a serious drag on Indian agriculture.

GARY V. NOREIKO, Ph.D. Southern California 1972. A portfolio approach to domestic and foreign investment.

Along with the estimation of rates of return traditional mean-variance portfolio analysis is modified and extended to consider skewness of distributions of rates of return. In applications to foreign and domestic investment the sophisticated three dimensional portfolio model of rate of return, variance, and skewness is found to generate efficient portfolios that give a better explanation than those from traditional mean-variance portfolio analysis.

FERNANDO J. OSSA, Ph.D. Cornell 1973. Payments problems in the economic integration of Latin America.

CONRAD M. OULETTE, Ph.D. Clark 1972. The theory and practice of ERP Counterpart Funds in the United Kingdom, 1948–1951.

Examined are the roles played by *ERP* local currency, together with the rationales given to Congress for the use of these funds when it was considering legislation for the *ERP* and predecessor aid programs. It is concluded that the principal use of these funds in the United Kingdom—to retire privately held government short-term debt—was in the main economically insubstantive, but local currency was used substantively in Germany to establish financial intermediaries.

ANDREW H. PARNES, Ph.D. Stanford 1973. Export instability and the direction of trade.

This study looks at individual trade flows from one economy to another to find the degree and causes of export instability in a sample of developed and less developed countries. Structural variable categories are composition of exports, commodity concentration of exports, and direction of trade. Additional variables measure development level of trade partners and value of trade flow. Using covariance analysis, the model indicates that less developed nations experience significantly higher export instability than developed countries and that choice of trading partners influences level of instability. Significant variables are level of commodity concentration and magnitude of trade flow. Higher concentration levels produce greater instability.

LORENZO L. PEREZ, Ph.D. Pennsylvania 1972. The export performance of the Latin American countries during the 1960's.

HOWARD C. PETITH, Ph.D. Rochester 1973. Joint production and the theory of international trade.

By careful consideration of the character of natural resources, it is shown that received theory implies that not more than 5 goods may enter trade, while actually over 30,000 do. A new model of trade is constructed based upon joint production and nontraded goods which alleviates this absurdity, and leads to a number of unorthodox and fairly robust results regarding the relative prices of nontraded goods and factors and the pattern of trade.

JONATHAN J. PINCUS, Ph.D. Stanford 1972. A positive theory of tariff formation applied to nineteenth century United States.

The effects of an import duty are nonexclusive, so I adapt public goods supply theory to explain the industrial pattern of tariffs. The focus is on appropriability of quasi rents, and on bargaining and transaction costs. I reinterpret the infant industry tariff phenomenon. An *OLS* study suggests it was a disadvantage in 1824, to be represented by few congressmen and senators.

ROBERT O. REID, Ph.D. Georgetown 1972. Border tax adjustments and international trade flexibility.

The thesis analyzes the effect of border tax adjustments on trade flows under various monetary and fiscal policies. A model was developed and used to estimate the impact of border tax changes on the trade balances of Western industrialized countries. The use of border taxes as a policy instrument was also considered.

HAK Y. RHEE, Ph.D. Kansas 1972. Optimal external debt for a developing economy.

The dissertation deals with a small country's optimum foreign debt over a finite planning horizon. The problem is analyzed in an economy with multi-outputs and multi-inputs. The input vector is divided into two subvectors, one of them being the domestic inputs and the other being the foreign inputs. The outcome of the analysis shows the condition under which the additional debt should be zero as well as other efficiency conditions along the optimum path.

MIGUEL RODRIGUEZ-VILLENAVE, Ph.D. Oregon 1972. Import substitution: The case of Venezuela.

GEORGE SAMUELS, Ph.D. Oregon 1972. The role of imports in growth: Selected Latin American countries, 1953–1967.

EDMUNDO SANCHEZ-AGUILAR, D.B.A. Harvard 1973. The international activities of U.S. commercial banks: A case study, Mexico.

The role of *U.S.* commercial banks in Mexico is examined. The volume of *U.S.* banks' claims on Mexico is estimated to be around $5,000 million. A close look at *U.S.* commercial banks' methods of operation abroad is presented, including the sources and profitability of foreign lending. Chraracteristics of *U.S.* bank loans to Mexico are enumerated. Finally, Mexico's ability to repay her external debts, present and future, is discussed in detail. Strong recommendations are made to the parties involved.

LUCIO P. SCANDIZZO, Ph.D. California (Berkeley) 1972. International capital movement and economic growth.

Economic growth and international capital movements are examined using a neoclassical model and in the second stage a dynamic post-Keynesian "two-gap" model. Trade and capital movements between a less developed country and a capital rich country with monopoly power are analyzed. Under conditions of a dominant trade gap, optimum paths of foreign exchange inflow are determined with the results applied to case studies of Argentina and India.

RICHARD W. SCHWINDT, Ph.D. California (Berkeley) 1973. The effects of economic integration upon industrial structures: The case of France, Italy, and West Germany.

GRANT M. SCOBIE, Ph.D. North Carolina State 1973. The effect of changes in the protective structure on the exchange rate: An analysis of the New Zealand foreign exchange market.

The underlying premise is that the exchange rate and the level of protection are a related pair of policy instruments for achieving external balance. The devaluation rate and the welfare gains associated with variable reductions in protection are estimated. The model is used to estimate the impact of British entry to the EEC on the New Zealand foreign exchange market.

KARNAIL SINGH, Ph.D. Western Ontario 1973. A monetary view of the balance of payments: An empirical investigation.

The empirical investigations reveal that in all the fourteen industrialized countries the balance-of-payments surplus is a positive function of the "sterilized" excess demand for money in the world as a whole; the extent of *U.S.* short-term liabilities to foreign central banks is a "system determined" phenomena; and the country demand for money functions are stable.

MILTON D. STEWART, JR., Ph.D. Texas (Austin) 1972. Foreign direct investments in the United States.

This study examines selected aspects of foreign direct investments in the United States, an area that has been apparently relatively ignored by scholars, general researchers, and popularizers alike.

ANDREW STOLLAR, Ph.D. Boston College 1973. Cotton textiles: An empirical evaluation of voluntary export restraints.

An attempt is made to evaluate the effects of the GATT sponsored long term arrangement regarding international trade in cotton textiles during two of the initial years of the arrangement (1964 and 1965). A spatial equilibrium model of international trade is used to simulate trade flows (and domestic consumption and production levels). The empirical results indicate that *LTA* (Long Term Arrangement) has had a restrictive influence on the exports of selected major Asian exporting countries.

SUK-TAI SUH, Ph.D. Washington (St. Louis) 1972. A general model of factor proportions theory of trade.

The dissertation is concerned with the following: to generalize the simple factor proportions theory in the case where commodities outnumber factors; to construct a new production function which is neoclassical in form but contains human capital as a third factor of production; to establish a new comparative advantage criterion in terms of the composite capital-labor share intensity; and to test the above for Korea, Japan, and the United States.

DAVID M. SWANSON, Ph.D. North Carolina (Chapel Hill) 1972. The demand for money and the balance of payments.

SUBHASH M. THAKUR, Ph.D. California (San Diego) 1972. Theory and estimation of speculative capital movements.

The traditional theory of forward exchange market and international capital movements is reviewed. A model of speculation when the currency is under speculative pressure is developed. A stock-adjustment model is then estimated for the United States using data for the period before the 1971 devaluation of the dollar. Impact of speculation on *U.S.* claims and liabilities is found to be substantial during this period.

MAHMOUD S. H. TOUBAR, Ph.D. Pittsburgh 1971. Elasticities of export supply in international trade.

JOSEF VAN BRABANT, Ph.D. Yale 1973. Bilateralism and intra-CMEA trade: 1949–1966.

EWEN M. WILSON, Ph.D. North Carolina State 1973. An elasticity analysis of the Rhodesian trade embargo.

An elasticity framework is developed to predict the welfare and exchange rate effects of the Rhodesian trade embargo. The notion of the uniform tariff equivalent is adopted to estimate price effects of the trade ban in the import and export markets. Explicit recognition is made of the importance of flue-cured tobacco in the Rhodesian economy.

Business Administration; including Business Finance and Investment, Insurance, Marketing, and Accounting

SURENDRA P. AGRAWAL, Ph.D. Florida 1973. The role of accounting in computer-based information systems.

This study presents a model of information systems that may overcome the deficiencies observed in the functioning of accounting and MIS. The proposed model would control its own input and output, provide for computerized as well as manual processing of data, and receive and utilize feedback from users, for its development. In addition to systems and O.R. specialists, it would include an expert in "information control" which may develop as a branch of accounting.

ERIC L. ANDERSON, Ph.D. Georgia State 1973. The buffer motivated production-to-stock decision and its macroeconomic implications.

This paper constructs a model to represent manufacturers' production-to-stock behavior with a sales buffer motive to determine the production flexibility in responding to unexpected sales. The model is tested on 6 two-digit S.I.C. industries that produce to stock—not to order. The resultant maximum likelihood estimators are then inserted in the basic Keynesian aggregate demand function to determine the macrodynamic implications of their behavior.

HENRY D. ANGELINO, D.B.A. George Washington 1973. An analysis of the U.S. Army's system for developing estimates of major equipment investment costs.

This research is a critical examination of the U.S. Army's cost estimating function for developing estimates of major equipment investment costs. The research supports conclusions that cost estimates recently prepared by the Army are timely, accurate, and complete. However, estimates have tended to be understated. Members of the cost community hold that staffing, organization, and operation of the cost function, facilitate preparation of accurate estimates.

ROGER M. ATHERTON, Ph.D. Michigan 1972. The impacts of centralization on performance and supervisory perceptions of centralization, attitudes, behavior, and effectiveness.

EMIL ATTANASI, Ph.D. Missouri 1972. Uncertainty in road construction: Implications for state highway agencies.

This study relates firm bid pricing behavior to industry bid distributions. Analysis of sequential bid pricing is conducted under behavioral assumptions identified with expected mark-up maximization and utility maximization. The influence of alternative regulatory policies, bidder risk attitudes and resource uncertainty is analytically examined. Properties of bid distributions are analytically examined and related to economic structure of the market, attitudes toward risk, and expectations of bidders. Bid data are then examined and provide a basis for comments associated with applied research in this area.

BRUCE N. BAKER, D.P.A. George Washington 1972. Improving cost estimating and analysis in DOD and NASA.

Surveys were conducted to determine cost estimating and analysis approaches and preferences within the Army Materiel Command, Air Force Systems Command, Naval Materiel Command, and National Aeronautics and Space Administration. It was found that most respondents distrust the parametric approach and have more confidence in detailed engineering approaches to cost estimating. Respondents called for several improvements in cost estimating but disagreed, on average, that 1970 procurement will result in less cost growth.

JIMMY D. BARNES, Ph.D. Oregon 1973. A strategic competitive bidding approach to pricing problems for petroleum industry drilling contracts.

ROBERT R. BELL, Ph.D. Florida 1972. The potential of pupillary response in business research: An investigation of methodology and autonomic contamination.

The debate over the use of pupil changes as indicators of physchological response cannot be resolved until methodological shortcomings are overcome. This study evaluated the validity of pupillometric technology, using real-time computer sampling of six physiological variables in a totally automated measurement system. Cost effectiveness studies of computerized methodology were conducted. Analysis showed that while pupillometric may be limited in general usefulness, computerized controls and measurements present advances in methodology, and can be economically justified.

URI BEN-ZION, Ph.D. Chicago 1972. Measures of risk in the stock market and the valuation of corporate stock.

The first part of the thesis analyzes the rate of return framework and the valuation framework of testing the "riskiness" of alternative risk measures. The second part analyzes the effects of investment in tangible assets, such as research and development and advertising, on the valuation of corporate stocks. The empirical work is done in a cross-section study, but it also analyzes a time-series measure of risk.

WILLIAM J. BRENNAN, Ph.D. Michigan 1972. Investment analysis and generally accepted accounting principles.

DOUGLAS B. BROWN, Ph.D. Michigan 1973. Modelling of retail patronage promotions—the practice and its value to management.

RICHARD W. CALLEN, Ph.D. Texas A&M 1972. A dynamic investment, production and financial model for a competitive firm.

In this dissertation, a discrete time control for production, investment, and finance is formulated for a perfectly competitive firm in a certainty world. The usual production function is not used. Instead, a linear process type of function is adopted. The model assumes linearity among the capacity variables. With these assumptions, an operational model for a multiproduct firm with multi-capacities under a form of capital rationing is developed. The firm is assumed to maximize its net wealth.

JOHN C. CAMILLUS, D.B.A. Harvard 1972. Formal planning systems: The control considerations in design.

The study examined the design implications of the purpose of facilitating the control of operations through formal planning. The basic proposition was that, in fulfilling this purpose, another important pur-

pose—namely, ensuring the stimulation and exercise of executive creativity—is adversely affected. An approach to the design of a segment of the corporate planning system, based on the proposed control/creativity tradeoff was developed and then revised on the basis of a survey of practices in over eighty corporations and interviews with practicing executives.

GEOFFREY O. CARLINER, Ph.D. California (Berkeley) 1972. Headship and ownership.

DARYL E. CARLSON, Ph.D. California (Berkeley) 1972. Financial analysis of institutions of higher education for policy decisions.

TING KO CHEN, Ph.D. Michigan 1973. Management transfer, management practice, and management performance—an empirical quantitative study in Taiwan.

PETER S. CHUNG, Ph.D. Northwestern 1972. Measurement and explanation of expected earnings to price ratios of common stock.

The major interest and focus of this dissertation is how to measure correctly "expected earnings" which appears in the numerator of the rate of return on common stocks. Four methods of measuring expected earnings were employed in the cross-sectional multiple regression analysis to explain different rates of return among the sample firms. The results show that the four methods provide better explanation for differential rates of return on common stocks than any other existing models.

JAMES J. CLARKIN, D.B.A. Harvard 1973. An investigation of a performance evaluation process.

This study examines data from performance evaluation records and from two personality tests with a questionnaire administered to 97 employees of a large government organization. The scores correlated closely with promotion decisions indicating reliance on minute differences. Better performers were distinguished from poorer only by the need to impress others, where they were brought up, and their number of siblings. There was dissatisfaction with communications about performance, and poorer performers felt more negative about their experiences and the promotion system in use. Poorer performers were also less self-confident and more negative about their future.

PHILLIP M. COLEBATCH, D.B.A. Harvard 1973. Manufacturing policy in the multinational enterprise: A mathematical study of sourcing patterns and their relationship to corporate financial goals.

This thesis examines production allocation, sourcing patterns and transfer pricing in the multinational enterprise, and studies their interaction with each other and with financial tools such as management fees, royalties, and internal dividend policy. Specifically, a mathematical model of a multinational corporation is developed and used as a basis to study these interactions, and to study the differences in the optimal choice of these quantities for two different objectives, consolidated profits and cash flow to the parent.

RICHARD C. CUBA, D.B.A. George Washington 1971. Relationships between technologists' motivation to perform, role perception and participative management: A study of engineering/scientific manpower utilization in R&D-oriented companies in the Baltimore-Washington area.

This research investigates the effects of role perception and participative management on the job performance of 600 engineers and scientists in five firms. Specific workday utilization patterns were secured to provide a measurement of the large existing mismatch between skills, interests, and job requirements. Sizable pockets of role uncertainty and laissez-faire management in the technical areas were uncovered. Organizational role clarification and participative interaction were found to be significantly related to higher performance levels and motivation to perform. Role orientation was also found to be flexible with age, experience, and traditional organizational rewards.

DAVID J. CURRY, Ph.D. California (Berkeley) 1973. An empirical test of relations between an individual's preference and similarity space of brands.

JEAN M. DAVID, Ph.D. Florida State 1972. A model for the efficient allocation of resources in a state university.

This dissertation applies an activity analysis model to the allocation of resources in a state university. The problem is first formulated as a linear programming model which serves as a first approximation and makes possible the mapping of the university's production possibility frontier. The model is then formulated as a non-linear program. A stochastic element is later introduced into the non-linear program. This is followed by a dynamic formulation with varying horizons.

DAVID F. DIANICH, D.B.A. George Washington 1971. An application of non-linear programming to approximate optimal management control decisions.

The research investigates a technique for optimizing management science models characterized as dynamic, non-linear, and constrained. The research integrates a classical solution procedure, the method of Ritz, in variational calculus, with contemporary non-linear programming techniques. The unknown dynamic decision function is approximated by a function of n variables, an n-dimensional polynomial, tranforming the model to an approximation in n-dimensions. Contemporary techniques of non-linear programming are used to optimize the transformed, n-dimensional model.

BERNARD C. DILL, D.B.A. George Washington. A regional study of existing developments in and between financial policy and financial operations at the headquarters level of selected large corporations.

This study concerns developments in the business finance function at the headquarters level. Matters

discussed concern ways in which the importance of the chief financial executive and other elements of financial management along with the relationships between financial policy and financial operations are changing. Discussed are ways in which changes in this function's environment and in the development of information technology are influencing this function. Interviews were conducted among 32 firms from *Fortune's 500 Directory.*

WILLIAM A. DIMMA, D.B.A. Harvard 1973. The Canada Development Corporation: A diffident experiment on a large scale.

The Canada Development Corporation was proposed to the Canadian Parliament in 1963 as an instrument of both economic nationalism and of gap-filling industrial development. It would operate under both private and public-sector influences. By 1971 and enactment, it had swung more solidly into the private sector and behind industrial development, partly reflecting a pervasive business ethic. However, the enabling legislation does not inhibit a future government, under some circumstances, for using the *CDC* for other purposes.

WILLIAM A. EARNER, D.B.A. Harvard 1973. An assessment of organizational elements that affect the introduction of a computer-based simulation into some organizational decision processes.

Introducing a complex, computer-based model to an organization not only affects the rational decision processes of that organization, but also the organizational system in which those processes are embedded. This thesis examines in detail two organizational decision processes in a bank about to implement a computer-based environmental simulation. These processes are described in terms of the segments of the decision processes interacting with four relevant elements of the organizational system. The thesis concludes with an assessment and prediction of model implementation in light of the interaction of decision processes and organizational system.

JON ENGLISH, Ph.D. Florida 1972. The use of a multivariate organizational behavior model in describing individual, group, and intergroup behavior: A comparison of three manufacturing firms.

The primary objective of this study is to describe and analyze behavioral patterns in organizations in terms of structural and leadership variables. A secondary purpose is to employ a new multivariate "systems" model that explains human behavior within an organization and to assess the operational feasibility of the model. Data on structural, leadership, and behavioral factors in three manufacturing plants were gathered from personal interviews, observation, and questionnaires. Each plant was described and contrasts in behavioral patterns were analyzed.

WALLACE FELDMAN, D.B.A. Harvard 1973. A study of selective marketing communication.

This thesis investigates the potential of advertising aimed at individuals or small recipient groups. It examines the development and use of increased audience selectivity capabilities in print, mail, and air media. An assessment of present constraints and possible future developments in message production and delivery technologies is made. The applicability of market segmentation concepts to selective communication strategies is discussed. Finally, an experiment assesses the possibilities of increased effectiveness of segment-specific advertising compared to advertising generalized for a total audience.

MARCO R. FIORELLO, Ph.D. California (Berkeley) 1972. Management and design tools for document retrieval systems: A method for predicting quantity output.

RICHARD G. FISCHER, D.B.A. Harvard 1973. Improving investment performance and the role of fixed-income securities.

Efficient portfolios of bonds and stocks are constructed using the Markowitz/Sharpe technique. For wide ranges of market conditions and portfolio risk levels, bonds play a much greater portfolio role than is commonly perceived. A large fraction of the bonds serves as a surrogate for a riskless asset and is relatively insensitive to the market outlook while the remaining bond investments may comprise a substantial proportion of the risky asset portfolio depending only on the pertinent market forecasts.

ROBERT J. GAYTON, Ph.D. California (Berkeley) 1973. A critical examination of presently accepted international accounting translation techniques.

LOUIS GILL, Ph.D. Stanford 1973. Iterative multilevel planning with aggregation.

Procedures are developed for plan preparation though explicit introduction of aggregation-disaggregation methods in standard "decentralized" planning procedures. A central planning bureau deals with aggregated quantities (prices and quantities of groups of products). Regional or sectoral bureaus are responsible for aggregating and disaggregating information. Production units are responsible for their choice of technique; they deal with disaggregated quantities which are the fine details of the plan. The utility function is of the Kantorovitch type.

STUART C. GILMOUR, D.B.A. Harvard 1973. The divestment decision process.

In this study divestment decisions were found to be the personally painful and organizationally difficult outcomes of a high level political decision process that made limited use of economically rational arguments. The study used four well-known management decision process models to look at the events surrounding divestment decisions in three large business organizations. Using these analyses, a model of the divestment decision process was constructed and implications for management and research were drawn.

JOHN H. GRANT, D.B.A. Harvard 1972. Management implications of systems-oriented strategies within selected industrial firms: A developmental model.

This research had as its objective the formulation and evaluation of a developmental model for analyzing four primary variables associated with the management of systems-oriented operations. Field research executed in five large corporations revealed that strategic, market, and technological factors are interdependent with, not determinant of the organizational structures surrounding systems work. Forces influencing changes in systems strategies and related research topics are discussed.

STEVEN D. GROSSMAN, Ph.D. Tufts 1972. Alternative theories of inventory investment.

THOMAS D. HINTHORNE, Ph D. Oregon 1973. Perceptual differences as a constraint on the implementation of management science techniques.

GERARD G. JOHNSON, D.B.A. Harvard 1972. The role of formal evaluation in the process of budgetary control.

In addition to accounting for the financial results of operations, the evaluation process must begin to take into account the feelings of the individual manager. This research project demonstrated that an important aspect of the evaluation process is the preparation it provides for future performance. Under varying economic conditions laboratory subjects who were so prepared outperformed those evaluated under the more traditional accounting variance format.

L. TODD JOHNSON, Ph.D. Michigan 1972. The auditor's responsibility for the detection of management fraud: Selected cases.

JOSEPH E. KASPUTYS, D.B.A. Harvard 1972. The influence of government profit policies on contractor management.

The Department of Defense determines profit objectives for negotiated contracts largely as a percentage of costs, without recognition of contractor assets. This policy should encourage contractors to act contrary to government objectives by keeping assets low and costs high. This was tested through a comparative study of defense and commercial operations, two questionnaires and research into the British asset-based system. The findings confirmed that existing profit policies are dysfunctional and could be improved through some consideration of assets.

JOHN B. KAYE, D.B.A. George Washington 1973. A test of the square root rule of stock price movement.

The study tests the hypothesis that the relationship between the price movement of low-priced and high-priced stocks during market rises and declines is mathematically consistent. Although prices move in different amounts, the square roots of prices move in equal amounts, on the average. The study fills deficiencies and gaps of earlier studies and investigates a new dimension: expected growth rate. It has implications for the *alpha* and *beta* of modern portfolio selection.

DIETER KLEIN, Ph.D. California (Barkeley) 1973. Dynamic behavior of adjustment processes.

JAY E. KLOMPMAKER, Ph.D. Michigan 1973. Sales forecasting for new industrial products.

CHARLES LILLIS, Ph.D. Oregon 1973. An investigation of the uses of non-metric multi-dimensional scaling in the identification and analysis of market segments.

JAY D. LINDQUIST, Ph.D. Michigan 1973. Retail store image and its role in the purchase decision process: An empirical study.

BRADLEY D. LOCKEMAN, Ph.D. Michigan 1973. The consumer information seeking process for a fashion good—An exploratory study.

NORMA M. LOESER, D.B.A. George Washington 1971. An examination of the top-level leadership strategy emanating from the executive branch of the government having an impact on the military-industry interface.

The study is oriented toward obtaining an explicit understanding of the military-industry interface through examining: the leadership authority and power of the President as chief of foreign policy and as commander-in-chief; the roots of *U.S.* military commitments abroad; the national objectives having defense implications as ascribed to the President; and the extent to which federal budget outlays for national defense generated growth in the defense establishment and defense firms.

RONALD W. LUNDQUIST, Ph.D. Oregon 1973. Organization and the seasons: An exploratory study of the structural and behavioral effects of seasonal employment fluctuations in the food processing industry.

NEIL E. MCNEILL, D.B.A. Harvard 1973. The use of profit as a measure in a nonprofit organization.

The study addresses the use of a constructed profit measure to improve performance in a nonprofit organization. The study applied a profit measure to three nonprofit Navy commissary stores while using three similar stores as a control group. The conclusion is that the technique is potentially useful, however, its effectiveness is sensitive to the degree of congruency existing between the organizational structure and the organizational purpose.

WILLIAM G. MISTER, Ph.D. California (Berkeley) 1973. Temporal additivity: A problem of accounting measurement.

JEFFREY H. MOORE, Ph.D. California (Berkeley) 1973. Peak-load allocation of a time-shared computer in a quadratic team.

JAMES R. MORRIS, Ph.D. California (Berkeley) 1972. The decision to purchase information for portfolio choice.

GERALD L. MUSGRAVE, Ph.D. Michigan State 1973. Economies of scale in computer centers.

IKUJIRO NONAKA, Ph.D. California (Berkeley) 1972. Organization and market: Exploratory study of centralization and decentralization.

DAVID P. NORTON, D.B.A. Harvard 1973. The centralization of information systems in large organizations.

The objective of the research was to determine if there is a preferred manner of assigning responsibility for the computer and associated tasks in various organization environments. The research, which was based on intensive case studies in two multi-divisional organizations, showed that economically rational arguments exist for various degrees of centralization or decentralization in specific environments. The organization forms dictated by economically rational arguments are frequently ignored in practice. The research explores the reason for this inconsistency.

JAMES A. OHLSON, Ph.D. California (Berkeley) 1972. The usefulness of accounting concepts based on accruals: A Bayesian approach.

JOSEPH R. PISANI, Ph.D. Maryland 1972. Automotive repair: A study of consumer and repair shop attitudes toward the industry, the performance of repairwork and regulation.

The dissertation reports the findings of a mail survey of the motor-vehicle-owning and repair shop populations of Prince Georges County, Maryland and Travis County, Texas. A general background on the automotive repair problem and a review of current literature on the industry are provided. The overall quality of warranty and nonwarranty repairwork was found to be substandard. Consumers and repair shops strongly favored regulation of mechanics and/or repair shops at the state level.

ROLLA W. RIDER, Ph.D. Oregon 1973. The marketing executive: A profile.

SIMCHA SADAN, Ph.D. California (Berkeley) 1972. The firm-investor interface: An inquiry into the role of accounting information.

DOUGLAS F. SCHOFIELD, D.B.A. Harvard 1972. The planning process in institutions of higher education.

Starting with a traditional four stage view of a planning process (goals, objectives, budgeting, evaluation), two sets of variables are identified as useful in analyzing a college planning process and in implementing improvements. One set pertains to planning functions in each stage, and the other pertains to the dynamic, integrated functioning of the whole process. Planning in two colleges is examined, and recommendations for management actions are made. Planning implications of three major trends in colleges' environments are discussed.

HENRY H. SEWARD, D.B.A. Harvard 1973. Measuring user satisfaction to evaluate information systems.

This dissertation proposes that the evaluation and design of information systems should be considered separately. Evaluation, if separated, may be conducted by less expensive means than design. The approach suggested is to evaluate by measuring user satisfaction with the information system. Satisfaction is considered to be directly related to the number of times the information system does not contain required information and the user must conduct an information search. The approach was tried and found feasible.

MARK G. SIMKIN, Ph.D. California (Berkeley) 1972. Mathematical programming for the state earmarking process: Tax policy in theory and an application for highway finance.

CHARLES C. SNOW, Ph.D. California (Berkeley) 1972. Environmental uncertainty and organization behavior.

SUSAN SOLOMON, Ph.D. California (Berkeley) 1972. Determination of satisfactory scale for data processing facilities.

ROBERT E. STERNENBERG, Ph.D. Houston 1972. A study of full cost versus marginal cost pricing of proposals to government agencies and their impact on contract award and performance.

WILL E STRAVER, D.B.A. George Washington 1971. A study of attitudes toward organizational loyalty.

Survey compares attitudes between employees from business government, military. Findings also analyzed by age, position, rank, seniority. Chi-square analysis on thirty-four attitudinal statements. Few significant differences found at .95 confidence level. Main content of statements shows similarity between loyalty enhancers and motivational factors. Organizational loyalty ranked fourth behind family, self, country. Supervisor found to be major loyalty object in each type organization. Respondents strongly questioned value of loyalty oaths.

WALTER J. STUART, JR., D.B.A. George Washington 1971. An empirical assessment of the managerial utility of certain general systems concepts: The savings and loan association.

This study seeks to make certain general systems concepts as applied to management more defensible by defining a savings and loan association as a system and examining the behavior of a large number of as-

sociations during a period of unusual reduction in net inflow of savings. Using the empirical results obtained the study applies these concepts to the problems of financial intermediation, designing a General System of Financial Investment Flows.

FREDERICK W. TEBBEN, D.B.A. George Washington 1971. Cash tender offers in 1967: A study of management and stockholder experience.

Cash tender offers, or take-over bids, that started in 1967 were studied from the standpoint of premiums offered, relationships of market prices and tender prices to book values, movements in stock and earnings growth rates and dividend incomes. One of the most important conclusions was that the mergers that followed tender offers had unfavorable results for both companies and stockholders. Earnings growth rates and stock prices suffered.

JOHN F. TOMER, Ph.D. Rutgers 1973. Management consulting for private enterprise: A theoretical and empirical analysis of the contribution of management consultants to economic growth in the United States.

The basic contention is that management consultants, due to their work for clients, contribute in many ways to economic change, which makes possible and "explains" a certain amount of annual economic growth. The analysis indicates that the lasting contributions of these consultants are types of human capital or, perhaps, organizational capital. Estimates of this capital formation and the resulting aggregate annual economic growth are made. Interviews in thirty-two management consulting firms provide the empirical basis.

JERRY A. VISCIONE, Ph.D. Boston 1973. The introduction of growth into the traditional theory of capital structure.

JAMES A. WALKER, D.B.A. Harvard 1973. Using analysis effectively in a complex decision process-planning NASA's planetary programs.

The problems of using systems analysis techniques to influence the outcomes of policy making in a complex organizational and political context are illustrated by case studies of attempts to apply such methods to long range planning for NASA's unmanned planetary programs. A method of enhancing the effectiveness of analysis in such settings by means of self-conscious "process-oriented approach" utilizing organizational, political, and psychological models as conceptual tools is proposed and discussed.

KENNETH D. WALTERS, Ph.D. California (Berkeley) 1972. Freedom of speech in the modern corporation.

BERNARD S. WATERMAN, D.B.A. George Washington 1971. Small business participation in federal government research and development—the government perception.

This study examines the attitudes of government technical and procurement personnel purchasing research and development (R&D) toward participation of small business in government R&D. It develops the views of these personnel regarding the availability and interest of small firms, potential measures of assistance, and small business performance. The government R&D purchasing community believes that small business lacks sufficient technical capability and does not mount a sufficiently aggressive marketing effort.

DAVID P. WEINER, Ph.D. Michigan 1972. The feasibility of obtaining an objective measure of the current value of land and buildings for disclosure in published financial statements.

ARMAND B. WEISS, D.B.A. George Washington 1971. Development of guidelines for the determination of economic retention stock in the federal government.

Six economic retention stock models are developed and compared with two other models and to *ERS* policies of the Defense Supply Agency and the General Services Administration. The *DSA* and *GSA* policies are found to be not economic. Six types of sensitivity analysis are made. The method of determining total quantity of stock to hold is derived. Decision tables are provided to cover a variety of situations.

RICHARD A. WERBEL, Ph.D. Michigan 1972. A multivariate analysis of brand loyalty for purchasers of new cars and major household appliances.

LAWRENCE M. K. WONG, Ph.D. Michigan 1973. Managerial ideologies in industrial society: The construction of the corporate world-view.

EARL M. WYSONG, JR., D.B.A. George Washington 1972. An analysis of the effectiveness of computer-based financial management systems in the civil agencies of the federal government.

The dissertation demonstrates: the complexity of requirements for federal financial management systems; some computer concepts available to handle the information requirements; and how federal agencies are handling the situation. Through the use of questionnaires, it was found that the capabilities of the computer have not been employed to a satisfactory extent. Although federal agencies' accounting systems provide the required financial information for external reporting purposes, they are deficient in providing information for managerial purposes.

CHUL KOO YUN, Ph.D. Michigan 1973. Transfer of American management know-how to foreign environments: Applying managerial budgeting system in Korea.

SIMON J. ZYSMAN, D.B.A. Harvard 1973. Top management and decentralized investment planning in diversified firms: A comparative study.

This dissertation is a comparative study of the top management role in major investment plans of two business units in each of three highly diversified *U.S.*

corporations of $500 million to $1 billion sales. The important variables selected to study are: the key participants in the investment planning process; interactions among the participants; the information available to them; and the organizational framework of the process.

Industrial Organization and Public Policy; including Economics of Technological Change, and Industry Studies

NISAR AHMAD, Ph.D. Washington State 1973. Economic utilization of road and rail transportation in Pakistan.

This thesis involves an attempt to examine Pakistan's transport pricing, regulatory, and investment policies from the point of view of economic efficiency. It found considerable evidence that the scarce resources devoted to transportation in West Pakistan were not utilized efficiently. Misallocations are found in passenger traffic and freight traffic services, and the pace of introduction of new transport technologies. A key area of misallocation pertained to the diversion of high-value freight traffic from rail to road transport.

STEVEN ANDERSEN, Ph.D. Rutgers 1972. Regulation, supply and cost in air transport: The domestic trunkline industry.

Scheduling behavior is examined under the assumption of imperfect cartelization through regulation. The model yields a functional relationship between load factor and fare, production cost, and a set of exogenous, demand determining variables. Estimation results, supplemented by an analysis of adjustment lags for costs of production, are used to evaluate changes in regulatory policy adopted during 1970, with particular emphasis on the tradeoff between fares, load factor, and rate of return.

PAUL R. AUERBACH, Ph.D. Wisconsin (Madison) 1973. Financial institutions and corporate control.

ROBERT BARRASS, Ph.D. Washington State 1973. The pre-1963 marketing of automobile tires by gasoline retailers: A problem of market power generated by franchise agreements.

This thesis investigates the implications of restrictions imposed by oil companies on the selection of brands of tires, batteries, and accessories by their franchised dealers. Franchising links the enterprise of small proprietors with the widely accepted brand names of large corporations, combining advantages of big and small business. Many restrictions are placed on franchisees and their purpose is brand protection, but these restrictions implement hidden surcharges, facilitate price discrimination, or extend the franchisor's monopoly power to additional lines.

JOHN H. BEEBE, Ph.D. Stanford 1972. Institutional structure and program choices in television and cable television markets.

The thesis constructs a model of product competition in television. It extends models by Steiner, Rothenberg, Wiles, and McGowan, and uses theories of spatial competition and public goods. The model compares program patterns of monopoly and competition under advertiser and subscriber support. Predictions refute Steiner's result that under limited channels and advertiser support monopoly provides greater diversity than competition, and shows the opposite for unlimited channels. Furthermore, pay TV promises programs closer to viewer preferences.

NAROTTAM BHARGAVA, Ph.D. Pennsylvania 1973. The impact of organization form on the firm: Experience of 1920–70.

RONALD S. BOND, Ph.D. Indiana 1972. Aggregate economic structure: Mobility, concentration, and mergers.

This dissertation is an economic and statistical analysis of aggregate mobility. The study of aggregate mobility reveals differences in the relative growth of the largest firms and provides a vehicle for analyzing the dynamics of aggregate concentration. Because past studies of aggregate mobility have been interpreted more often in a market than in an aggregate context, the relationship between aggregate mobility and changing aggregate concentration has received little attention. The oversight is important.

JOHN D. BOWMAN, Ph.D. West Virginia 1972. Trends in the location of glass production.

EDWARD A. BRANCH, D.B.A. George Washington 1972. A study of selected procurement practices of small firms in metropolitan Washington, D.C. engaged in federally financed research and development.

This is a study of small Washington-based R&D firms that are currently engaged in federally financed R&D. The study develops a profile of selected organization, manpower, and marketing characteristics of the firms; examines the small business-government contracting process in terms of types of contracts used and preferred and methods of contract placement used and preferred; and examines the attitudes of Washington-based firms toward government contracting.

KEITH J. BREWER, Ph.D. McGill 1973. The Canadian east coast groundfish industry.

DAVID C. BUNTING, Ph.D. Oregon 1972. Rise of large American corporations: 1896–1905.

FOSTER BURTON, Ph.D. Pittsburgh 1972. A regional economic model of the construction industry.

This study relates construction in place in a time period to craft labor resources and the optimal mix of stocks of the several types of structures in a region by the use of a linear programming model. The importance of craft habits to the linear assumption is emphasized. Unemployment is examined and it is con-

cluded that some, previously assumed to be weather-related, is caused by shortages in a few crafts and is therefore structural.

BO A. W. CARLSSON, Ph.D. Stanford 1972. The measurement of efficiency in production: An application to Swedish manufacturing industries 1968.

The study attempts to bring together various definitions of efficiency in the economic literature; integrate inefficiency into standard microeconomic theory; measure efficiency empirically at the plant level in 26 Swedish manufacturing industries; and analyze the results in terms of macroeconomic variables. It is found that tariffs are negatively and the concentration ratio positively associated with efficiency, indicating that in a small, open economy the concentration ratio reflects economies of scale and specialization rather than market power.

GARY D. CARMAN, Ph.D. Southern Methodist 1973. Nuclear and gas-oil power plants as investment alternatives.

This study examines investment criteria by which regulated electric utilities choose new power plants. By means of sensitivity analysis, conditions are determined which make nuclear plants more economical than gas-oil plants.

MOHAMMAD A. CHAUDRY, Ph.D. Tufts 1972. The economics of competition in the U.S. communications industry: An econometric approach.

MICHAEL E. CONROY, Ph.D. Illinois (Urbana) 1972. Optimal regional industrial diversification: A portfolio analytic approach.

DANE J. COX, Ph.D. Cornell 1973. Toll road pricing: Theory and application.

ANTHONY W. CYRNAK, Ph.D. West Virginia 1972. The effect of regulation on external diseconomies: Surface mining in northern West Virginia, 1960–1970.

VICTORIA A. DAILEY, Ph.D. Virginia 1973. The certificate effect: The impact of federal entry controls on the growth of the motor common carrier firm.

This study sets forth a theoretical model of motor common carrier behavior with respect to investment in route authorizations. Under the present system of federal (ICC) controls of entry and route expansion, there will be a tendency for large motor common carriers to experience both greater growth and slightly lower costs than their smaller competitors. Econometric investigation of the two major hypotheses suggests that the model's implications were valid for 1958–68.

MICHAEL G. S. DENNY, Ph.D. California (Berkeley) 1972. Trade and the production sector: An exploration of models of multiproduct technologies.

LARRY J. DOBESH, Ph.D. Washington State 1973. Earnings control standards for regulated motor carriers.

This study examines the ICC standards for regulating the earnings of truckers. It determines whether the permitted earnings have been reasonable in terms of economic criteria. The ICC has employed irrational and biased standards to test the earnings of regulated truckers since the passage of the Motor Carrier Act of 1935. The operating-ratio standard provided no meaningful indication of the reasonableness of the earnings of regulated truckers. Deregulation of motor transport would offer the best solution for earnings control of trucking firms.

JEFFREY C. DONAHUE, Ph.D. Florida State 1972. The product and utilization alternative for bark in Florida and the costs of bark processing operations.

With few exceptions forest products firms in Florida traditionally have considered tree bark a waste wood-residue product generated under joint cost conditions with other marketable primary forest products such as sawlogs and pulp chips. The purpose of this study is to provide the comprehensive economic analysis which hopefully will enable forest products firms to achieve a greater, more proper utilization of their bark, and, concommitantly, enhance the development of the bark industry in Florida.

LOISJEAN DRAKE, Ph.D. Nebraska 1972. A statistical analysis of hospital costs in Nebraska.

This study provides evidence regarding economies (diseconomies) of scale in the general hospital industry using cross-section data for 68 community hospitals in Nebraska. Long-run average cost functions estimated for the fiscal years 1967–68 and 1968–69 exhibit behavior contrary to that predicted by economic theory. Diseconomies of scale predominate, with some tendency for average costs to decline after hospitals reach a size of about 330 to 400 beds.

DALE S. DRUM, Ph.D. Nebraska 1972. An economic analysis of the public power system in Nebraska.

Nebraska is the only state in the nation in which the entire electrical generation, transmission, and distribution system is publicly owned. Analysis reveals that plants are, in general, too small and rate policies ill-adapted to achieving high utilization. Thus, the comparatively low electrical rates in Nebraska are apparently attributable to the tax advantages of public ownership or to the failure of commissions in other states to exert effective earnings control.

GARETH P. DYAS, D.B.A. Harvard 1972. The strategy and structure of French industrial enterprise.

The thesis describes the evolution of strategy and structure, in France's 100 largest manufacturing companies, between 1950 and 1970. The main trends observed were towards increasing levels of product line diversity, and towards the eventual adoption of divisional forms of organization. They were explained in terms of economic, institutional, and cultural environmental factors. These trends have led to recent change

in the way of life within firms, with dramatic implications for French management.

WILLIAM R. EADINGTON, Ph.D. Claremont School 1973. The economics of gambling behavior.

Nevada is presently the only state with legalized casino gambling, although a number of other states are actively considering legalization. This study constructs a behavioral model of Nevada's tourist gambler and tests the model's implications against the four main resort areas. It is argued that the type of gambling motivation (entertainment or investment) depends mainly on income level. Predictions of the likelihood of success of casinos in other states are drawn from the model. Economic impact of gambling on Nevada is also discussed.

THOMAS W. EWART, Ph.D. Purdue 1972. Biddings for oil leases: A simulation approach.

MOHAMED A. FINAISH, Ph.D. Southern California 1972. Libya's petroleum policy.

It is argued that the typical oil producing country can be conceived as engaged simultaneously in a bargaining game with oil companies and a competitive game with other exporting countries. Within this framework, the Lybian government's petroleum policies since 1955 are analyzed and evaluated. Then, alternative strategies available for oil-exporting countries, chiefly increasing host country participation and nationalization, and their advantages and limitations are discussed with special reference to Lybia.

THOMAS S. FRIEDLAND, Ph.D. California (Berkeley) 1972. Advertising and concentration.

PETER V. GARROD, Ph.D. California (Berkeley) 1972. Service and employment implications of food distribution: A study of the retail sector of Santiago, Chile.

The dual role of the distribution sector of providing market services and employment opportunities is examined. The existing fragmented, small-scale structure characteristic of the low-income regions is compared with the more capital intensive mass-merchandising operation characteristic of the high-income regions. Welfare comparisons indicate that the gain in consumer surplus resulting from the lower prices charged by the large-scale operations would more than compensate the displaced employees of the existing small firms if these firms were to be replaced by the larger more labor efficient operations.

MALCOLM M. GETZ, Ph.D. Yale 1973. The incidence of rapid transit in Atlanta.

PHILLIP E. GIFFIN, Ph.D. Tennessee 1972. Industrial concentration and firm diversification in bituminous coal with special reference to the southeastern United States, 1950–1970.

This study presents an analysis of concentration and changes in concentration in bituminous coal. The approach is to view concentration in various markets with major emphasis on a southeastern submarket. Concentration figures are made available for buyers and sellers. The study also presents data on coal firm diversification. Essentially, the findings indicate rising concentration levels in addition to increasing diversification. Another contribution of the study is the method and data supplied in defining a submarket.

PAUL R. GILON, Ph.D. Southern California 1972. A constrained price discriminator: An application to the U.S. Post Office.

In this study the behavior of a profit maximizing third degree price discriminator operating in two markets is analyzed. The firm is further subject to the constraint $P_1 = (1\text{-}d)P_2$, where d is a policy set discount rate and P_1 and P_2 are the prices. Specifically, the impact of the discount rate d is examined under various assumptions. Subsequently, as an application, the theoretical models are fitted with 30 years of U.S. Post Office data. Finally, various conclusions with their respective assumptions are presented and discussed.

ROBERT S. GOLDEN, Ph.D. California (Berkeley) 1972. Optimal hedging decisions for beef cattle feeders.

The study is concerned with the development of a cattle purchase-hedging decision model. The model draws on the mean-variance approach to asset selection and Holbrook Working's theory of hedging storable commodities. Price expectations are required for the model and are formalized through the use of an econometric forecasting system. Spectral analysis is used in the identification and estimation of the system. The study is concluded through an example of the use of the model.

ALICE W. C. GORLIN, Ph.D. Michigan 1973. Soviet firms and the rationalization of the shoe industry of the *USSR*.

JAMES W. GOTCHER, JR., Ph.D. California (Berkeley) 1972. A systems approach to policies governing the design of an information dissemination system for the earth resources technology satellites.

ROBERT T. GREUBEL, Ph.D. Arkansas 1973. An evaluation on the performance of the electrical machinery industry: A case study of an industry.

The null hypothesis is that the action taken on the part of the government in the electrical conspiracy case did not make any difference in the performance of the transformer industry. In many ways the preconsent and postconsent time periods exhibit no difference in the performance variables analyzed. The possibility that collusive and noncollusive oligopoly may produce the same results and the data used may render this conclusion an over-simplification.

ROBERT HALVORSEN, Ph.D. Harvard 1973. Residential demand for electricity.

Long-run elasticities of demand are estimated with pooled cross-section data. Because price is a function

of quantity purchased, a simultaneous equations model is estimated by *TSLS*. Estimates of long-run elasticities are robust. Electricity price is the most important determinant of demand. Short-run elasticities are estimated for individual states with time-series data. The short-run estimates are sensitive to the choice of dynamic model.

HOMER J. HOLLAND, D.B.A. George Washington 1972. On the relative accuracy of the Delphi method as an aid in technological forecasting.

An experimental study examining the relative accuracy of three methods: Delphi, Committee, and Questionnaire, for eliciting responses from groups of experts. The study concludes that groups produce more accurate estimates when they use the Delphi Method as compared to the Committee or Questionnaire Methods.

WASFY B. ISKANDER, Ph.D Indiana 1973. The economic potential of copper in the Arctic.

This study presents an analysis of the economic potential of copper in the Canadian Arctic, also referred to as the North, during the 1973–1985 period. The study deals specifically with the Yukon and Northwest territories. The primary purpose of this study is to provide guidelines for appropriate amounts and direction of new investments on infrastructure for copper production.

MD NURAL ISLAM, Ph.D. McGill 1973. Interregional competition and comparative location advantages of North American newsprint industry.

GLENN P. JENKINS, Ph.D. Chicago 1972. Analysis of rates of return from capital in Canada.

The principal objective of this study is to estimate the rates of social and private return and effective taxation that are produced by physical capital in Canada. This information is developed on a detailed sectorial breakdown for the years 1953 to 1969, and is used to evaluate the taxation gains from foreign owned capital, the social opportunity cost of public funds, and the economic cost of distortions created by the nonneutral taxation of income from capital.

PHILIP J. KARST, Ph.D. Washington (St. Louis) 1972. The effect on performance of the separation of ownership from control.

PETER KEMPER, Ph.D. Yale 1973. The location decisions of manufacturing firms within the New York metropolitan area.

MANFRED KIMMLE, D.B.A. Harvard 1972. Design of management information systems: An approach and case study.

This thesis examines how one should determine the content and structure of a management information system (*MIS*) to support executive decision makers in managing the overall business. It presents a normative framework for *MIS* design, demonstrates its application at a large hospital organization, and provides an authoritative appraisal by a panel of experts. As precedents rather than prescriptions, the propositions and findings should point the way to more effective *MIS* elsewhere—in the health care sector, in government, and in private industry.

GEOFFREY R. KING, Ph.D. Southern California 1972. Arbitration of technological change.

This study investigated the reported industrial labor arbitration cases involving technological change between 1960 and 1970. The cases were analyzed for evidence of guiding principles and a common thread of rulings. The analysis covered union and company contentions, and the results of those contentions. There were eight conclusions from the study.

CAROLE E. KITTI, Ph.D. Chicago 1973. Patent policy and the optimal timing of innovations.

REUBEN KYLE III, Ph.D. Tennessee 1972. Seller concentration, price competition, and nonprice forms of competition in consumer goods industries.

A number of theoretical analyses are consistent with the hypothesis that sellers tend to substitute nonprice competition as seller concentration increases. A test of the hypothesis was devised using price flexibility, defined in various ways, to represent the extent of price competition and advertising as a proxy for all forms of nonprice competition. A sample of forty consumer goods industries offered support for the hypothesis.

JULIAN E. LANGE, Ph.D. Harvard 1973. The bidding process in the construction industry.

A general framework for the analysis of the bidding process in construction is developed. The framework is then applied to the bidding process in a specific industry submarket: i.e., state-initiated building construction in Massachusetts. Multiple regression techniques are employed to explain variations in contractor bids. The results suggest that the approach is a fruitful one and indicate certain promising avenues for extensions of the research.

DAVID P. LEVINE, Ph.D. Yale 1973. Accumulation and technical change in Marxian economics.

EDWARD B. LEVITON, Ph.D. State University of New York (Binghamton) 1973. A cash flow theory of conglomerate mergers.

This paper explores the hypothesis that with passage of the Celler Kefauver Amendment (1950), effectively eliminating vertical and horizontal merger opportunities, the conglomerate form of merger has developed as an attempt to maximize growth consistent with profit maximization. Results of multivariate analysis appear to support the assertion that cash flow generation did play significant role in explaining merger activity during 1960's.

CHANTEE LEWIS, D.B.A. George Washington 1972.

Simultaneous equation production functions (Cobb-Douglas type) for decisions pertaining to seabased tactical air.

The need for analytical aids to assist management in making input allocation decisions concerning the operating of military aircraft is quite clear. A number of authors have suggested that a Cobb-Douglas type production function exists in this situation. An exponential model is postulated and five aircraft cases are analyzed. R^2 of .884 to .951 were obtained. The paper concludes that an exponential model is appropriate for military aircraft capital versus labor investment decision.

CHARLES A. LUCKETT, Ph.D. Georgtown 1973. A model of the markets for automobile sales and credit.

Three alternative models are developed to explain quarterly automobile unit sales and credit, 1961–70. The best performing model contains four equations, solved recursively, for yearly changes in auto sales, credit extended, the Commerce Department's Buying Intentions Index, and a loan terms index based on contract maturities and down-payment percentages. Loan terms prove a significant determinant of credit usage. Buying intentions and employment variables are found superior to income variables in explaining sales.

RUFUS A. LYMAN, Ph.D. Northwestern 1972. Demand conditions in the electrical power industry: An econometric study.

The dissertation investigates demand conditions in the residential, commercial, industrial, and public street and highway lighting categories of customers. Data are for utilities and were collected for the period 1959–68. The model is specified with a general functional form of which the linear and log-linear forms are special cases; non-linear regression methods are used. Results of interest concern the specification of interaction terms, climatic variables, and income distribution variables. Also of interest are price elasticities and income redistribution effects.

THOMAS W. MASON, Ph.D. Pittsburgh 1972. The effects of entry: A study of the American aluminum industry.

This thesis examines the effects of the structural changes due to the entry of new firms into primary aluminum production in the United States. Alternative models of price determination are formulated, and their predictions are compared with the actual prices for primary aluminum ingot for the years 1923–40 and 1947–68. Results indicate that the entry of additional manufacturers brought about changes in conduct and lower prices for virgin aluminum in the postwar market.

JOHN C. MOORE, JR., Ph.D. California (Berkeley) 1972. The least cost organization of cotton ginning facilities in California's San Joaquin Valley.

The basic objective of the study was to determine the size number, and location of cotton gins in the San Joaquin Valley that would minimize assembly and processing costs. Costs were developed through the cost synthesis approach and the final solution was derived using a variation of the linear programming transportation model. The analysis included extended ginning seasons and seed cotton storage. It was found that San Joaquin Valley cotton farmers could reduce costs considerably if the least cost system were adopted.

FREDERICK J. E. MORRISSEY, D.B.A. George Washington 1972. The law and licensed lending: Georgia in the 1950's.

The twin objectives were to portray the personal loans market served by the consumer finance industry and to determine the bases for the high ranking in loan service of the industry in Georgia. The market in Georgia was found to be not one market, but to comprise three distinct, noncompetitive markets. The high degree of loan services were ascribed to: the historical evolution of consumer finance in the state; the present law which provides for borrower's protection, handsome charges, and generous loan ceiling; and the liberal interpretation of the convenience and advantage clause.

RICHARD D. MURPHY, Ph.D. Michigan 1972. The determinants of the extent of multiplant operation in U.S. manufacturing industries.

ROBERT H. NICHOLSON, Ph.D. North Carolina State 1972. An economic evaluation of alternative food service systems for the North Carolina Department of Correction.

This study examines the relative costs of alternatives to the food delivery system operated by the North Carolina Department of Correction. After describing economic relationships among expenditure categories, and identifying technologically feasible systems, partial budgeting techniques are used to select the food delivery system offering maximum budgetary savings. A centralized production and distribution system operated by Department of Correction personnel was found to give the lowest projected budget. The future possibilities of wage payments for inmate labor and use of noninmate employees in the central commissary do not change this conclusion.

YUKIO NOGUCHI, Ph.D. Yale 1972. An economic theory of diffusion of knowledge.

YEUH-YUN CHENG O'BRIEN, Ph.D. Illinois (Urbana) 1973. Intertemporal equilibrium models of a monopoly and the analysis of tax effects.

GERALD W. OLSON, Ph.D. Rutgers 1973. Consumer demand for services in the United States, 1947–69.

Five dynamic models of consumer demand for services are tested to determine the causes for the rapid growth of service expenditures and service prices since 1947. Using the results of these estimates, expenditure

projections and policy simulations are made to determine the optimum set of policy actions to stem the inflationary pressure arising from the service sector.

FRANKLIN L. ORTH, JR., Ph.D. Tennessee 1970. An empirical analysis of the relationship between diversification and profitability in the 1000 largest industrial corporations, 1965.

HOWARD E. OVERCAST, Ph.D. Virginia Polytechnic Institute 1973. The survivor technique: Reappraisal and revival.

The survivor technique here uses a statistically consistent chi-square test to compare the temporal distribution of plants. Minimum efficient size is estimated by a statistical rule which is based on a hypothesis concerning the relevant distribution. This rule yields results somewhat similar to those obtained previously. The particular advantages of this particular appraisal are: a longer time period, a larger sample, and the use of a consistent statistical rule rather than a rule-of-thumb.

UN-SUH PARK, Ph.D. Pittsburgh 1972. A study of technical progress in the U.S. aggregate economy.

The biased disembodied technical progress under neoclassical production function model is inconsistent with the near constancy of the share ratio if strict constancy of the elasticity of substitution is adhered to. Certain law of movement of elasticity of substitution is established. The varying elasticity of substitution is also estimated by capturing the shifting characteristics of *CES* production functions in a way which is statistically consistent. This also leads to the estimation of biased technical progress.

ROBERT A. PITTS, D.B.A. Harvard 1972. Variable incentive compensation for division general managers in diversified companies.

This thesis compares variable incentive compensation schemes for division general managers in eleven large diversified firms, six of which have grown primarily through internal development (Borg-Warner, Corning Glass Works, General Electric, Honeywell, 3M, and Westinghouse), five primarily through acquisition of other companies (AMF, Gulf & Western Industries, ITT, Midland-Ross, and Sybron). Incentive compensation awards for division general managers are found to be generally more affected by corporate performance, subject to more top management discretionary influence, larger, and subject to a wider payoff range in the former than the latter group of firms.

RAWLEIGH H. RALLS III, D.B.A. George Washington 1971. A time-series analysis of the nature of the demand for life insurance.

This study investigates at the industry level the relationships that exist between aggregate consumption and savings and the sale of life insurance products. Investigation at the company level is also carried out with data of considerably more detail than that available at the national level. The investigations reveal that protection appears to be purchased when savings are high, and the savings component of a life insurance product appears to be purchased when consumption is rising.

FREDERIC D. RANDALL, D.B.A. Harvard 1972. Corporate strategies in the drug industry: A study of strategic response to social and political pressures.

This thesis examines strategic response within firms in one industry that has experienced significant social and political pressures. It describes what strategies emerged and why. Field research was conducted in six drug firms to determine strategic response in several areas of activity. Strategies fell into one of three patterns depending on each firm's internal characteristics in two key areas—innovation and vulnerability. These dictated strategies in product, marketing, pricing, management, finance, and in consumer and government relations.

ANTHONY A. ROMEO, Ph.D. Pennsylvania 1973. Interindustry differences in the diffusion of an innovation.

JOSEPH M. ROOP, Ph.D. Washington State 1973. The economic organization of state agricultural experiment stations.

The behavior of a specific type of nonprofit organization, state agricultural experiment stations, is examined. The analytical tool is derived from that branch of the theory of organizations most closely associated with the names of Chester I. Barnard and Herbert A. Simon. The inducements-contributions approach to organizational theory is used to develop a behavioral and structural model of experiment station activity. The model is capable of generating independent evidence bearing on a number of the suggested hypotheses.

HARVEY ROSENBLUM, Ph.D. California (Santa Barbara) 1972. The structural determinants of merger activity: 1948–1968.

GEORGE R. SANDERSON, Ph.D. Stanford 1972. The differential impact of macroeconomic conditions on industry profits.

JULES J. SCHWARTZ, D.B.A. Harvard 1973. The decision to innovate.

Exploratory field studies in two high-technology firms confirmed the applicability of Bower's resource allocation model to technological innovation decisions. Managers contributed to problem solving by articulating strategy, negotiating criteria and preparing supporting business plans. They managed risk by factoring problems and imposing schedules in return for their support. Large rewards to innovators were legitimized by sharing responsibility for outcomes. Proposals assumed a conservative bias and were incremental rather than radical in nature.

ELLIOTT D. SCLAR, Ph.D. Tufts 1972. The public

financing of transportation in the greater Boston area.

JOHN J. SIEGFRIED, Ph.D. Wisconsin (Madison) 1972. The relationship between economic structure and the effect of political influence: Empirical evidence from the Federal Corporation Income Tax Program.

This study attempts to demonstrate that systematic empirical analysis is possible for the important issues overlapping the area of political science and economics. The sample consists of 1963 corporation income tax information and economic variables aggregated by IRS "minor industry." In general, it is found that firm size is negatively correlated with the effective average corporation income tax rate; market concentration and the profit rate are positively related to the tax rate; and industry size and the geographical dispersion of an industry's employment are not associated with variations in the tax rate.

JAMES H. SOOD, D.B.A. George Washington 1972. A study of the international computer industry and a projection of the effect of the American computer industry on the U.S. balance of payments from 1969 to 1975.

It is anticipated that the American computer manufacturing industry will have an increasingly larger impact on the *U.S.* balance of payments in the future. This study is concerned with the development of the projection of the effect of this industry on the *U.S.* balance of payments from 1969 to 1975. This projection should then provide a more complete understanding of the economic and financial strength of the United States during this period.

JOHN R. STODDEN, Ph.D. Illinois (Urbana) 1972. Firm size, industry structure, and cost of capital.

HORST SYLVESTER, Ph.D. Michigan 1972. New and used cars as consumer alternatives.

RICHARD F. SYRON, Ph.D. Tufts 1972. An analysis of the collapse of the normal market for fire insurance in substandard urban core areas.

DAVID J. THOMSEN, Ph.D. Oregon 1973. The analysis of conglomerate performance.

DAVID TIERNEY, Ph.D. Temple 1972. Employment effects of textile imports.

THOMAS F. TORRIES, Ph.D. Pennsylvania State 1972. Economic descriptions and simulation of the construction aggregate industry in the Allentown-Bethlehem-Easton area of Pennsylvania.

The industrial and chemical stone industry is described in economic terms. The demand for industrial and chemical stone is forecast for the Allentown, Bethlehem, Easton, Pennsylvania area for the years 1968 to 1975. The potential study of raw materials to satisfy the demand for aggregate materials is identified in the study area. A computer simulation model is constructed and operated to select the most profitable supply areas. An optimal solution occurs when the overall gross cost to the consumer is minimized and the profits of all the individual producers are maximized, subject to all producers receiving a specified minimum rate of return on sales and subject to all demand for all materials being satisfied.

JOHN M. TRAPANI, Ph.D. Tulane 1972. The role of money in the theory of production: A theoretical and empirical analysis.

The purpose of this thesis is to develop and test a microeconomic model that explains the sources of productivity of money balances held by firms. It is shown conceptually that money balances conserve on entrepreneurial effort in acquiring conventional inputs, and that such balances may reduce unit production costs. This implication is tested using cross-section samples of electric utilities and the above hypothesis cannot be rejected. The influence of monetary intensity upon the firm's equilibrium capital-labor ratio is also analyzed theoretically and empirically.

ANTONY B. T. WERNER, Ph.D. Pennsylvania State 1973. The financing of the Canadian metal mining industry, 1945–1960.

The demand for and supply of funds to the Canadian metal mining industry in the 1945 to 1960 period is examined. Foreign demand for Canadian mineral products is considered to have provided the chief stimulus for the expansion of the Canadian metal mining industry. Techniques used to finance the mining industry are outlined. Returns to net capital are found to have declined, as did returns to investors between 1954–59 and 1960–65. No definable relationship is found to exist between risk and reward in the case of the Canadian mining industry.

ROBERT L. ADAMS, Ph.D. Illinois (Urbana) 1972. An economic analysis of the junk auto problem.

ANTONIO AGUIRRE, Ph.D. California (Berkeley) 1972.

Welfare cost of protection: The fertilizer industry in Argentina.

The object of this study is to analyze the situation of the nitrogenous fertilizers industry in Argentina, which is an example of the implementation of the industrialization policy via import-substitution. An attempt is made at estimating the lower limit of the welfare cost of protection of this "infant" domestic industry. Finally, an evaluation of the social costs and benefits of alternative policies is made and its implications analyzed.

MUDDATHIR A. AHMED, Ph.D. Arizona 1972. Electronic data processing as a tool in farm management: A case study of Arizona AMAP users.

The bulk of electronic data processing programs now in use by both public and private agricultural concerns are directed at the following three objectives: to supply records for tax and financial purposes; to supply cost and return analysis for enterprises and general farm management; and to provide a source of data for research and educational purposes. However, actual use by farmers is concentrated on the first objective.

DOUGLAS R. A. BECK, Ph.D. Iowa State 1972. Water quality and community viability.

This project determines implications for regional growth when water quality parameters were imposed on specific industries. A quantitative model was developed as the basis for computer simulation of an eight-county Iowa F.E.A. to provide information and projections for use in planning service and industrial development under water quality constraints. An environmental impact program permits an analysis of major demographic-economic interactions, their relationship to water quality controls and their impact on specific sectoral reallocations of employment, output, and investment within the regional area.

JACQUES BLAS, Ph.D. Missouri 1972. Economic analysis of the influence of resources restrictions on farm output and total income in a region of Spain.

ALDO L. BIONDOLILLO, Ph.D. Minnesota 1972. Social cost of production instability in the grape-wine industry: Argentina.

MICHAEL F. BRADLEY, Ph.D. Cornell 1973. Proposal for long-term apple processing marketing contracts.

This study analyzes traditional grower-processor relationships in the apple industry and the problems associated with price making. Included are price and cost differentials for specific quality variations which form the basis for long-term forward formula pricing. The study concludes with model contracts including a number of alternatives to satisfy individual grower-processor needs.

MAURICE H. BRUCKER, Ph.D. Illinois (Urbana) 1973. Computer-based retirement planning system for farmers with low income.

CLARK R. BURBEE, Ph.D. Minnesota 1972. Adjustments to improve the competitive position of the upper midwest turkey industry.

BRUCE O. BURNHAM, Ph.D. Colorado State 1972. The economics of technical change: With special emphasis on Colorado agriculture.

Development and application of methodology which quantifies the impact of resource development and technological change on gross output in the agricultural sector of a multi-county region has lagged the specification of similar models at the national level. In an attempt to narrow the gap, this thesis develops economic models which relate gross output to intermediate inputs and technical change inputs for the agricultural sector of Colorado and multi-county regions of the state.

GERALD R. CAMPBELL, Ph.D. Michigan State 1973. Procurement contracting and sow leasing as vertical coordination arrangements in the hog-pork subsector.

JOSÉ L. CARVALHO, Ph.D. Chicago 1972. Production, investment and expectations: A study of the United States cattle industry.

Conciliation between production and investment theories is attempted through the use of a dynamic model which implies profit maximization over time. The maximization problem is solved with the help of an IBM/360 by means of a computer language, FORMAC, which allows algebraic manipulations. Expectations formation about future prices prove to be very important for the profit maximization, and a "quasi-rational" model based on time-series analysis is proposed. Empirical tests are performed with satisfactory results.

SEAN B. CHIN, Ph.D. Missouri 1972. Exhaustible resources and technological change in U.S. agriculture, 1940–1969.

JON M. CONRAD, Ph.D. Wisconsin (Madison) 1973. Uncertain externality: The case of oil pollution.

Many substances which generate external diseconomies also involve elements of uncertainty; specifically, the extent of the divergence between social and private cost may not be known in the present. This phenomenon was entitled uncertain externality and was seen to arise from random elements of certain synthetic and natural systems. Oil pollution is a special case of uncertain externality. The uncertainty arises from: random elements of the (synthetic) closed subsystem; unpredictable physical conditions present

when a spill occurs; and incomplete biological information on the effects of crude and refined oils on marine populations.

SANDY A. D'AQUINO, Ph.D. Colorado State 1972. Optimum allocation of natural resources.

This study develops a general formulation of a deterministic linear programming model that can be applied to management of resource systems. This deterministic model would, in turn, be related to a stochastic model which would determine discount rates for "risk" in coefficients of the resource model. The study had three main objectives: to assist managers in optimum allocation of resources; to adjust allocation of resources as a result of variance-covariance in coefficients of the model; and, to calculate necessary adjustment in the discount rate as a result of variance-covariance in product prices.

LEROY DAVIS, Ph.D. Illinois (Urbana) 1972. Relationship of market structure to spatial and temporal pricing patterns in the grain industry.

ALVIN J. DE BOER, Ph.D. Minnesota 1972. Technical and economic constraints on bovine production in three villages in Thailand.

Thai bovine production has lagged behind the rest of agriculture. A one year study of three Thai villages was used to model village bovine resource allocation. Marginal value products of crop production resources were estimated and charged against bovine enterprises. Internal rates of return were estimated for ten types of production represented. These indicated few inefficiencies in the existing system. Further models were constructed incorporating technical change and its likely effects on the system.

RALPH D. ELLIOTT, Ph.D. North Carolina State 1972. The industrial demand for water and waste treatment in selected U.S. cities which are levying surcharges.

A study of thirty-three cities which have been levying surcharges based on the strength of industrial wastes showed that these charges provide a worthwhile incentive for firms to recover or otherwise dispose of wastes that are now flushed away with water. Industrial demands for water and waste treatment are both negatively related to marginal charges for water and surcharges, as expected. Elasticities are thought to fall in the range of —0.5 to 1.0.

JOHN C. GAMBLE, Ph.D. Illinois (Urbana) 1973. Economic evaluation of the impact of alternative environmental regulations and waste management systems on Illinois hog producers.

GERALD L. GEHRE, Ph.D. Arkansas 1973. The measurement and role of dairy producer's economic perception and attitudes toward class I base plans.

The primary objectives of this study were to measure dairymen's economic perception and attitudes and to relate these attributes along with socioeconomic variables to preferences for base plans. Some of the statistical tools employed were Mann-Whitney U-test, chi-square and multiple regression. Conclusions were that policy makers should consider: regional variances in perception and attitudes; the "free rider" problem in a voluntary base plan; and attitudes and socioeconomic factors in developing an economic program.

ADAM GIFFORD, JR., Ph.D. California (San Diego) 1972. Environmental issues and economic growth.

Pollution, natural resource constraints, and recycling are considered within the context of aggregate growth models. The analysis describes the types of reactions the economy can make when confronted with such environmental problems. The results suggest the possibility of maintaining a viable environment along with economic growth.

GURMUKH S. GILL, Ph.D. California (Berkeley) 1972. Demand and supply of wastepaper with policy implications for quality of the environment.

Employing available empirical evidence, a case is made for increased recycling of wastepaper in urban refuse. Despite this, increased recycling is considered unlikely until economic constraints on the reuse of wastepaper are recognized and removed. To help identify such measures, the demand and supply functions for wastepaper in the United States are econometrically estimated and the computed elasticities are used as measures of relative effectiveness of various constraints. Some measures to reverse or offset the identified constraints are recommended while others are suggested for further investigation.

RICHARD D. GREEN, Ph.D. Missouri 1972. Expectation formulations and optimal decisions in cattle feedlot problems.

ELLIOT S. GROSSMAN, Ph.D Rutgers 1973. National and state level econometric models of the U.S. asparagus industry, 1948–1969.

An examination of static supply and demand models on the national and state levels including farm level relationships for all asparagus, and for fresh and process asparagus taken separately. Included are forecasts for 1970 and 1980. A production function is estimated using the pooling method. A geometric distributed lag model of the national all-asparagus supply is estimated via a modification of Wallis' method and by Dhrymes' double search method.

JORGE GUTIERREZ-VILLARREAL, Ph.D. North Carolina State 1972. Investment alternatives in the processing of North Carolina apples.

The profitability of a variety of apple processing activities was evaluated for three sizes of plants operating for three lengths of season. Initial investment, equipment specifications, and operating costs were calculated for single and multiple-product plants which produced canned slices, sauce, frozen slices, juice, vinegar, concentrate and essence and apple butter. Calculated internal rates of return indicate that juice and juice-sauce in combination have the greatest profit potential. The effects of level of raw and finished product prices, conversion rates and raw product availability on rates of return are examined.

TEKETEL HAILE-MARIAM, Ph.D. Stanford 1973. The production, marketing, and economic impact of coffee in Ethiopia.

Coffee accounts for more than 50 percent of Ethiopia's export earnings and nearly 13 percent of its monetary *GDP*. This analysis measures the coffee industry's gross value-added and net contributions to national income, contributions of foreign exchange and savings to noncoffee sectors, and linkages with the domestic economy. Findings are that the popular view that Ethiopian coffee comes from natural forests is incorrect; the supply of coffee is low relative to domestic and export demand, and export demand and expansion of exports have not been seriously constrained by the world quota system.

OSMAN A. HAKIM, Ph.D. Arizona 1972. The effects of the U.S. cotton policy on the world market of extra-long staple cotton.

The Sudan of which the author is a citizen is one of the major producers of extra-long staple cotton. On the other hand, the United States is the world's largest producers of cotton. The *U.S.* cotton policy is assumed to have some effects on the world market for extra-long staple cotton.

ALLAN J. HARRIS, Ph.D. Kansas State 1973. Economic incentives in dryland crop-share leases, western Kansas, 1951 and 1970.

WAYNE HAYENGA, Ph.D. Michigan State 1973. The effects of bank mergers on financial services available to rural Michigan residents.

ROBERT B. HELMS, Ph.D. California (Los Angeles) 1973. The effectiveness of Federal Power Commission regulation of the field market for natural gas.

The effectiveness of the FPC's regulation of the natural gas field market is tested by estimating supply relationships for the period 1945–60 and then comparing projected and actual prices and reserves for the period 1961–69. The study concludes that area rate regulation caused a shortage of gas only after 1967. The control of field prices is shown to have provided an monopsony benefit to regulated pipelines at the expense of natural gas producers and consumers.

RICHARD C. HOYT, Ph.D. Minnestoa 1972. A dynamic econometric model of the milling and baking industries.

This dissertation encompasses variables such as the *U.S.* demand for baked products, domestic and export demand for wheat, *U.S.* and foreign wheat production capabilities, domestic and overseas demand for hard red winter and spring wheats, and the domestic demand for millfeed in a simulation framework in order to determine, for example, the impact of different hypothetical government programs on crop prices and prices and profits in the milling and baking industries. The model is also amenable to experimentation with respect to any of the other approximately 100 variables contained therein.

JAMES D. HOWELL, Ph.D. Ohio State 1973. Large farm organization in east central Ohio.

ROBERT D. HUNT, Ph.D. Minnestoa 1972. The contrasted effects of quota, autarky and free trade policies on U.S. beef production and prices.

The study attempts to estimate the effects of the U.S. Meat Import Quota on *U.S.* beef prices and production and make some assessment of the resultant welfare costs. A block recursive system consisting of a single equation beef import sector and a simultaneous equation domestic beef production and consumption sector was estimated. Analysis showed welfare costs to be significant though not large. The income transfer effect was also estimated and related to the social cost of the transfer mechanism.

FRANCIS S. IDACHABA, Ph.D. Michigan State 1972. Marketing board taxation of Nigerian agriculture: Some implications.

BOUWO M. JELLEMA, Ph.D. North Carolina State

1972. Analysis of the world market for groundnuts and groundnut products.

Using a market simulation model, which included twenty-five country groups and four seasons of the year, the most profitable markets and seasonal trade flows were identified for all exporters of groundnuts under free trade conditions taking into account costs of transportation and storage. The effects of various tariff policies of the *EEC* and the United Kingdom were calculated in terms of changes in producer and consumer surpluses and in government revenues. The overall net effects of the tariffs were found negligible, but the income transfers substantial.

FARRELL E. JENSEN, Ph.D. Kansas State 1972. A comparison of demand and factors affecting consumer acceptance of fresh and frozen meat as determined from a retail market test.

RICHARD E. JUST, Ph.D. California (Berkeley) 1972. Econometric analysis of production decisions with government intervention: The case of the California field crops.

Decision theory and the economic theory of risk-bearing are used to develop an econometric model of decisions made with changing risk. The effects of government farm programs are then included. The model is used to investigate the effects of government programs on acreage decisions in California. Acreages regulated directly by marketing quotas appear to be highly influenced by their programs while crops with voluntary programs are influenced more by risk and quotas for competing crops.

JAMES B. KLIEBENSTEIN, Ph.D. Illinois (Urbana) 1972. An economic analysis of the effects specialty grains should have on production decisions made by farmers.

PHILLIP L. KNOX, Ph.D. California (Berkeley) 1973. The U.S. beef cattle industry: A policy analysis with costs of adjustment theory.

The three segments of the study are the development of a theoretical model including costs of adjustment for input changes, the estimation of the model, and the application of the model to the evaluation of current beef import policies. In the imperfect, dynamic setting with largely naive expectations, producer incomes were found to decrease as a result of the beef quota on importation. Slow adjustment negated immediate income gains and overadjustment for the longer period resulted in lower prices and income.

JERRY J. KROPF, Ph.D. Missouri 1972. Social indicators of efficiency and equity convergence in four distressed regions.

HYDER A. G. LAKHANI, Ph.D. Maryland 1972. Some static and dynamic relationships between economic development and environmental quality.

This study attempts to find the nature and extent of relationship between economic development and environmental quality. The static framework hypothesizes an inverse relationship between economic development and environmental quality by means of transformation curves and social indifference curves and tests it by multiple regression equations for air quality in 100 *SMSA*s. The dynamics postulates a Gompertz function for diffusion of environment-saving techniques in petroleum refining and tests it by two-stage least squares.

STEVEN M. PEASE, Ph.D. Yale 1973. The spatial agricultural economy: A theoretical study with special reference to Brazil.

FREDERICK M. PETERSON, Ph.D. Princeton 1972. The theory of exhaustible natural resources: A classical variational approach.

A partial equilibrium, present value maximizing model of an extractive industry is solved by classical variational methods with the assumption of continuous time, perfect certainty, and an infinite time horizon. The basic model is augmented to include technical progress, exploration, and recycling. The effects of monopoly, externalities, and tax policies on the time paths of exploration, mining, recycling, and prices are determined by a priori reasoning and by numerical analysis.

DAVID C. PETRITZ, Ph.D. Illinois (Urbana) 1972. Economic implications of the effects of climatic stress on shelter alternatives for finishing cattle.

ALLAN P. RAHN, Ph.D. Iowa State 1973. A quarterly simulation model of the livestock and poultry subsectors for use in outlook and price analysis.

This study develops a systematic procedure for generating intermediate term outlook information for use by decision makers in the five major meat producing industries in the United Utates. These five industries include those producing beef, pork, lamb and mutton, broiler and turkey meat. The procedure utilizes a 47-equation open structural system econometric model which is designed to be operationally manageable and capable of satisfying the "online" temporal requirements of an active outlook information program.

JAVAD M. SADEGHI, Ph.D. Michigan State 1972. An economic analysis of alternative corn irrigation systems in southwest Michigan.

MICHAEL A. SALANT, Ph.D. Stanford 1973. A strategy for operating the upper Pampanga irrigation project: A case study in dynamic optimization involving risk.

An adaptive stochastic model for a dam-reservoir irrigation system is constructed and solved to determine the optimal planted area, throughout the crop year, for irrigated rice production. The model overplants initially to take advantage of possible wet years, but cuts back to avoid crop failure if the year is dry. The adaptive stochastic model is compared, using historical simulations, with various nonadaptive stochastic models and with a deterministic model. Implications for double-cropping are discussed.

HORMOZ SALEH, Ph.D. Cornell 1973. An econometric analysis of the demand for animal protein in Iran.

Cross-sectional data from four household consumption surveys was used to determine the demand for mutton, beef, poultry, and fish in Iran. The effect of income distribution on the demand for animal protein was analyzed by use of a log-normal frequency distribution in conjunction with the Lorenz coefficient. The analysis indicated that the demand for mutton will exceed internal production by approximately 195 thousand tons annually by 1979.

GRANT W. SCHAUMBURG, Ph.D. Harvard 1973. The Paretian model: An application to the Syracuse air pollution problem.

This thesis tests the Paretian model through an application to the Syracuse, New York air pollution control problem. The Paretian model is a mathematical method of generating Pareto optimal outcomes of a bargaining-oriented public decision process. It can be used either as a descriptive and predictive tool, or as an alternative to conventional benefit-cost analysis. The test results indicate that the Paretian model is a potentially valuable tool for applied economics and systems analysis.

DAVID L. SCOTT, Ph.D. Arkansas 1973. The economics of environmental pollution: The case of the electric power industry.

An investigation into the types of residuals, methods of abatement, and costs of control of pollution for the electric power industry. Both fossil-fuel and nuclear plants are examined and control expenses are estimated in terms of costs that consumers can expect to pay in the form of higher bills. The study includes recommendations concerning the industry and environmental control and an overview of economics and pollution.

EUGENE P. SESKIN, Ph.D. Carnegie-Mellon 1973. The social costs of air pollution.

LEONARD A. SHABMAN, Ph.D. Cornell 1973. Decision making in water resource development and the potential of multi-objective planning: The case of the Army Corps of Engineers.

Decision-making processes for four projects are evaluated with a model of political choice processes including factors affecting information transmission and reception. Use of multiple objective optimization models for project formulation and evaluation is then evaluated. Changes necessary to the success of multiple objective evaluation are in regional organization, personnel, hierarchy and regulations, data management systems, criticism and review, public participation, cost sharing plus authorization and appropriation policy.

SURJIT S. SIDHU, Ph.D. Minnesota 1972. Economics of change in wheat production in Punjab (India).

The study focuses on an evaluation of the change in production and cost relationships of wheat crop resulting from the introduction of Mexican varieties of wheat in the Indian Punjab during the latter half of 1960's, and compares economic efficiency of small versus large wheat farms and tractor-operated versus nontractor operated ones. The neoclassical theory of production and profit functions is the basic tool for the analyses.

GEORGE W. SILVERTHORNE, Ph.D. California 1973. Optimal production from a seaweed resource.

DUNSTAN S. C. SPENCER, Ph.D. Illinois (Urbana) 1973. The efficient use of resources in the production of rice in Sierra Leone: A linear programming study.

PHILIPPUS H. SPIES, Ph.D. Iowa State 1973. Management of water quality through selected institutions and instruments.

Water quality management is discussed in terms of planning, organization-coordination and control. Arguments of planning are discussed by means of a model as applied to the Upper Skunk River Basin in central Iowa. Instruments for water quality control are compared. It is concluded that charges for point pollutants and treatment standards for diffussed sources are the most efficient. A general P.T.O. framework for organizing and coordinating water quality management is proposed. The basis of this proposition is free group formation and a hierarchy of constitutions.

THOMAS H. STAFFORD, Ph.D. Cornell 1973. Methods and costs of distributing beef to the food-service industry.

An exploratory cost study of the more common channels of distributing beef to the institutional market. The more common practices and requirements of food-service establishments, beef handlers and packers are identified and examined in separate chapters. A comparison of nine common systems together with a conceptualized cost model serves to identify possible areas of gaining distribution efficiencies. The study concludes with suggested areas for further research in distributing beef to the food-service industry.

ROSCOE E. STOUT, Ph.D. Iowa State 1973. Land as a competitive asset and capital proxy.

An analysis of the degree of substitution between farm real estate and financial assets and the implications of a strong substitution relationship toward the strength of monetary policy. The demand for farm real estate is estimated with time-series data with statistical tests of significance and constancy of regression coefficients over time. A three-asset general equilibrium model is tested using land as a proxy for capital.

MOHAMMED I. SULIEMAN, Ph.D. Missouri 1972. Economic implications of the withdrawal of diethylstilbestrol from cattle feeds.

CHARLES R. TAYLOR, Ph.D. Missouri 1972. Dynamic evaluation of pest control strategies.

GORDON T. C. TAYLOR, Ph.D. California (Berkeley) 1973. An economic analysis of governmental air quality controls.

LLOYD D. TEIGEN, Ph.D. Michigan State 1973. Costs, loss, and forecasting error: An evaluation of models for beef prices.

REMIGIO D. TORRES, Ph.D. Minnesota 1972. Potential benefits and pricing of irrigation water: A case study of the Santa Cruz system.

An economic model was developed to determine the net contribituion of irrigation water to rice output under different levels of rainfall availabilities. The computed value amounted to about P1,275 per hectare during dry season cropping and P934 for the wet season. Shifting the cropping period by one month earlier than traditional starting dates would result in irrigating an additional 1,100 hectares during the dry season. The monetary net return associated with this shift was equivalent to P1.36 over the entire irrigation system of 4,000 hectares. The shift calls for a degree of water management higher than what now prevails.

TIMOTHY F. TREGARTHEN, Ph.D. California (Davis) 1972. Air pollution: An economic analysis.

ALAN H TSAO, Ph.D. Iowa State 1972. Spatial equilibrium and regional comparative advantages in American agriculture.

The linear programming model (2,100 x 8,056) of 15 consuming regions and 138 production areas includes all major crops and livestock products. Regional comparative advantages were identified in the components of shadow prices—production cost, transportation cost, and resource opportunity cost. The two solutions were analyzed on different levels of land and labor constraints (commercial farms vs. all farms): Production shifts to areas with strong comparative advantages. Small farms contribute resources to production in most areas.

STEPHEN E. VAHOVICH, Ph.D. Temple 1973. A framework for evaluating the effect of environmental management policies.

BELLUR V. VANKATAKRISHNA, Ph.D. Kansas State 1972. An economic analysis of processing whole milk into butter and by-products with the continuous churn in Kansas.

PURUSHOTAM L. WAHI, Ph.D. Illinois (Urbana) 1972. An econometric analysis and temporal price equilibrium of U.S. soybean oil.

WILLIAM A. WARD, Ph.D. Michigan State 1972. Native models for estimation of indirect employment and profit gains resulting from public water project investment.

KARL E. WEDEMEYER, Ph.D. Southern California 1972. Interstate natural gas supply and intrastate market.

This dissertation analyzes the interrelationship between jurisdictional and nonjurisdictional markets for natural gas. Interstate contract prices were constrained by Federal Power Commission price ceilings from 1966 thru 1969. Field markets for gas were basically competitive over this period. Excess demand appeared in the interstate market during the early 1970's. The study concludes that the interaction of jurisdictional and nonjurisdictional price and volume behavior affects the outcome of regulatory decisions.

Manpower, Labor, and Population; Including Trade Unions and Collective Bargaining

JOHN P. ADAMS, JR., Ph.D. Claremont School 1973. Training the hard-core unemployed: An evaluation of a union sponsored MDTA program.

This dissertation involves an economic evaluation of the Transportation Opportunity Program—an MDTA demonstration project designed to improve labor market prospects of the severely disadvantaged minority unemployed in the Los Angeles area, with the Southern California Teamsters providing major support for training administration and job placement. Project evaluation entailed estimation of program pay-out for the individual trainee, and examination of trade union support as a determinant of program success.

ROY D. ADAMS, Ph.D. Illinois (Urbana) 1972. A two-sector model of doctorates in higher education.

ROBERT F. ALLISON, Ph.D. Michigan 1972. The role of the nurses' aide.

GOSPEL S. ANGAYE, Ph.D. Pittsburgh 1972. Population and economic development in Nigeria.

This dissertation defines the major demographic and economic features of Nigeria and examines very critically the implications of population size, structure, and rate of growth for Nigeria's economic development. The results of a computerized economic-demographic model show that reduced fertility is favorable to economic and social development in Nigeria.

RICHARD B. ANKER, Ph.D. Michigan 1973. Socioeconomic determinants of reproductive behavior in households of rural Gujarat, India.

MICHAEL W. BABCOCK, Ph.D. Illinois (Urbana) 1972. Employment implications of alternate federal spending priorities for the Illinois economy.

CLIFFORD H. BAKER, Ph.D. North Carolina State 1972. The lagged effect of minimum wages on teenage unemployment.

The lagged effects of minimum wage legislation on teenage unemployment from 1948 through 1968 are investigated by use of a distributed lag econometric model and by use of a partial adjustment model. The distributed lag model is critically examined and shown to possess certain deficiencies in explanatory power. The partial adjustment model is then developed and shown to overcome some weaknesses of the distributed lag model and to improve the understanding of the adjustment process.

THOMAS A. BAROCCI, Ph.D. Wisconsin (Madison) 1972. The drop-out and the Wisconsin apprenticeship program: A descriptive and econometric analysis.

This study examines the various determinants of an individual's success or failure in an apprenticeship program, and investigates whether or not cancellation of the indenture really represents "failure." I employ econometric models to predict the likelihood of success in an apprenticeship, by taking full account of the apprentice's personal and occupational characteristics, as well as opinion indices and labor market indicators corresponding to the time of the apprenticeship. Pre-apprenticeship experience and education and post-apprenticeship employment and income data are also used in the analysis.

ROBERT D. BROGAN, Ph.D. North Carolina State 1972. The determinants of interindustry wage variation.

Average hourly earnings variation by occupation across industries is examined. Three hypotheses are tested in a model based on labor-leisure tradeoffs and labor productivity. The ability to pay hypothesis is in general rejected. An establishment size hypothesis based on work atmosphere disutility is accepted for semiskilled workers. The evidence is generally consistent with a quality difference hypothesis. Capital intensity has predictable effects upon wages by skill class across industries.

ELVIN O. CAMPBELL, Ph.D. Oklahoma State 1972. An evaluation of the performance of workers with impairments at the Oklahoma City air material area.

An annual performance appraisal standard score is used as a surrogate for labor productivity. Impaired workers are compared to nonimpaired control groups by annual wage ranges ($1,000 intervals) and also by occupational groups. The establishment where the study was conducted is a mass employer of the impaired, thereby permitting comparison by impairments which could be treated statistically. The t-test was used to determine the significance of the results.

THOMAS M. CARROLL, Ph.D. Syracuse 1973. Educa-

tion and the distribution of income and wealth among individuals.

The thesis presents a theoretical model with two labor groups: one possessing a single skill, the other also a second skill acquired through education. A homogeneous output can be produced by a production function which uses natural labor skill or another requiring "educated labor." After relating education and labor heterogeneity through the asymptotic distribution of income, attention is given to distributional effects of private and public educational finance.

CRAIG G. COELEN, Ph.D. Syracuse 1973. Properties of the adjustment equation in a model of the demand for workers.

A number of studies, using optimal control techniques, have been made of the properties of adjustment equations in investment. These studies can be extended by analogy to adjustment equations in models of employment behavior. A simple optimal control model of employment behavior is developed in this paper. Explicit adjustment equations are derived for the case in which labor requirements are expected to fluctuate seasonally and secularly over the planning horizon.

C. MARIO M. CORTES, Ph.D. Washington (St. Louis) 1973. Technological absorption and unemployment: A comparative study.

ROBERT W. DACUS, D.B.A. George Washington 1971. Minimizing unemployment welfare costs through the stimulation of unskilled labor employment.

To define a general wage policy which will permit welfare reform while maintaining economic incentive to work if able, manpower and welfare programs, along with pertinent wage theory, are reviewed and a general wage policy is defined providing for the following: a. guaranteed annual income; b. all-inclusive minimum wage; and c. wage subsidies to all workers at minimum wage level. A mathematical model is derived to optimize parameters of above program. *BLS* and census data are used to estimate costs of the program.

JULIE S. DAVANZO, Ph.D. California (Los Angeles) 1972. A family choice model of U.S. interregional migration based on the human capital approach.

This model of migration as an investment in human capital has the following features: financing costs play an important role in determining the optimal investment in migration; for married persons the decision-making unit is the family rather than the individual; in the empirical analysis a wider range of demographic groups, including women and nonwhites, is considered; and some new explanatory variables, e.g., an income-distance interaction term and military indices, are considered (and are statistically significant) in the econometric model.

GORDON W. DAVIES, Ph.D. Michigan 1972. An economic-demographic simulation model designed to test the effects of changes in the rate and skill composition of net immigration on the Canadian economy from 1952-1968.

DOUGLAS N. DAY, JR., Ph.D. California (Berkeley) 1972. Mediation: A multi-stage learning model.

CARL L. DYER, Ph.D. North Carolina State 1972. College and university student migration.

The objective was to study the migration of college students in the United States using 1963 cross-section data by state. Three alternative ways of defining migrants led to three models. The results indicated that tuition and fees, per capita income, and number of colleges in the home state were important determinants of migration across all models. School quality and student ability within the home states were significant variables in some of the models.

KARL A. EGGE, Ph.D. Ohio State 1973. White-black differences in hours of work supplied among men 45 to 59 years of age.

The purpose of this research was to determine if and why the labor supply of black men differed from that of their white counterparts. The data were the 5,000 men 45 to 59 years of age in the first survey (1966) conducted by the U.S. Bureau of Census for the Center for Human Resource Research at the Ohio State University.

THRÁINN EGGERTSSON, Ph.D. Ohio State 1972. Economic aspects of higher education taken under the World War II GI Bill of Rights.

In the study human capital theory is used to evaluate the U.S. government's massive investment in higher education under the World War II GI Bill. The chief data source is a 1967 Census Bureau survey of veterans. Findings include estimates of the impact of the GI Bill on the nation's stock of human capital; regression analysis is used to explain the variance in earnings of veterans; and rates of return to college for veterans are found.

NAZAR S. EL-ISSA, Ph.D. Maryland 1972. Urban unemployment and labor market structure in the process of industrialization.

NADIA H. ELSHEIKH, Ph.D. Oklahoma State 1972. Graduate education for economic development: An evaluation of patterns and trends of specialization of Latin American students in the United States.

The major objective of the study is to discuss and evaluate the patterns and trends of specialization of graduate students from selected Latin American countries (Argentina, Brazil, Chile, Colombia, Mexico, Peru, and Venezuela) in *U.S.* universities in terms of their relevance to their home countries' development needs and employment opportunities. The second objective is to compare and contrast the contribution of each of the graduate students' sponsor groups to the home countries' economic development through their influence on students' specialization.

ALLAN FELS, Ph.D. Duke 1972. The British Prices and Incomes Board: The NBPI as an instrument of incomes policy administration.

PETER FEUILLE, Ph.D. California (Berkeley) 1973. Police union power.

GARY S. FIELDS, Ph.D. Michigan 1972. A theory of education and labor markets in less developed countries.

BOB G. FIGGINS, Ph.D. Arkansas 1973. Intergenerational occupational socioeconomic status mobility of selected 1965 Missouri high school graduates.

Workers are divided into groups according to sex, education level, and person reported by the worker as being the most help in the choice of an occupation. Analysis leads to the following conclusions: a difference in status mobility exists that is attributable to the person reported by the worker as the major influence in occupational choice; workers reporting teachers/counselors as major influencers have a higher percentage of upward mobility than other workers.

GADSDEN C. FRAMPTON, JR., Ph.D. South Carolina 1973. Industry wage discrimination: Additional evidence.

This study, based on the 1966 Survey of Economic Opportunity, attempts to measure the nonwhite wage differential of employees within thirteen industry groups.

ROBERT H. FRANK, Ph.D. California (Berkeley) 1972. The supply of labor.

WILLIAM S. FRANKLIN, Ph.D. Texas (Austin) 1972. An analysis of traditional routes of entry into selected construction unions.

This study of bricklayers, carpenters, electricians, ironworkers, plumbers and steamfitters, and sheet metal workers in Atlanta, New York City, and Austin, has shown that admissions policies resemble each other among locals of the same international union, but vary widely intracity among locals of different internationals. Minority groups seeking access to the trades are at a disadvantage compared with whites, because whites are more likely to know people in the unions and to know how to use the traditional routes of entry. Minorities need to undersand how the traditional routes function in order to increase their participation in the construction industry, but there is also a need to develop new routes to expedite minority employment.

DONALD E. FREY, Ph.D. Princeton 1972. Wage and employment effects of collective bargaining in public schools in New Jersey.

A static equilibrium model of the wage and staffing decisions of school districts was developed. Implications of the model were used to specify wage and employment equations. Wage equations estimated from data from 300 districts in New Jersey showed that recent collective bargaining has had a negligible impact on teachers' wages and employment. The only important determinant of teachers' wages is other wages in the labor market where district is located.

CONRAD F. FRITSCH, Ph.D. Cornell 1973. An evaluation of the economic effects on New York agriculture from the extension of unemployment insurance to the agricultural sector.

This study reviews the development of unemployment insurance and the exclusion of the agricultural sector. It assesses the likely cost of unemployment insurance for agricultural workers, to the State Trust Fund, to dairy farmers and to fruit farmers in New York. Dairy and fruit were selected to represent types of farms using large and small amounts of seasonal labor. The agricultural sector estimated cost rate was similar to the statewide cost for presently covered nonagricultural employers.

MILES E. GALVIN, Ph.D. Wisconsin (Madison) 1972. Collective bargaining in the public sector in Puerto Rico.

The first part of the study provides a cursory description of the long-run dynamics of Puerto Rican society. The second part analyzes the legal factors in support of unilateralism, discusses the factors contributing to employee acceptance of unilateralism, describes how the transition to bilateralism is being accomplished, and analyzes the process of collective bargaining in government employment. The conclusion is that resistance by the Puerto Rican government to extension of industrial democracy to its own employees is resulting in social disruption which appears to outweigh the temporary developmental advantages accruing from imposed austerity.

ROBERT J. GASTON, Ph.D. California (Los Angeles) 1972. A human capital model of age at first marriage in the United States: An econometric study.

ROBERT W. GLOVER, Ph.D. Texas (Austin) 1972. Development and upgrading minority contractors: The Atlanta and Houston experiences.

This paper is an empirical study of minority business enterprise in construction. The analysis is based on a survey of black contractors in Atlanta and black and Mexican-American contractors in Houston. This study outlines the characteristics of the minority contractors, describes their future plans and aspirations, details the problems they face in improving or expanding their businesses. Three approaches to upgrading the minority contractor are examined: government assistance; joint venturing and mergers; and the minority association. Recommendations are made for future public policy.

CLAUDIA D. GOLDIN, Ph.D. Chicago 1972. The economics of urban slavery: 1820 to 1860.

Urban slavery in the antebellum South declined during the last decade before the Civil War. This led many to infer that urbanization and slavery were in-

compatible and that the South did not urbanize because of slavery. I find that the demand for urban slaves was strong during the period 1820 to 1860 and that slaves were pulled out of the cities by rising profits in agriculture. The remainder of the dissertation treats other interesting aspects of urban slavery.

CLARENCE L. HAM, Ph.D. Southern California 1972. The influence of other peoples' schooling on an individual's income.

A theoretical basis was developed for the expectation that the schooling of other people would affect an individual's income. This theoretical construct showed that the schooling of community members should affect an individual's income through market responses and that schooling of the cooperating work group should have effects both through market responses and through spillovers. Multiple regression analysis on the data of the one-in-one-thousand sample of the 1960 Census of Population confirmed these expectations. The effect was relatively more important for minority group members, *certeris paribus*.

GERALD HAREL, Ph.D. Temple 1973. Wage development in Israel 1948–55.

PHILIP J. HELD, Ph.D. California (Berkeley) 1972. The migration of the 1955–1965 graduates of American medical schools.

SYDNEY H. HIGH, Ph.D. Duke 1972. Changes in occupational wage differentials in the United States: 1940–1960.

STEFAN N. HOFFER, Ph.D. Illinois (Urbana) 1972. The determinants of women's earnings.

LAWRENCE R. HUDSON, Ph.D. Syracuse 1973. Measurement of human capital in the 1959 U.S. population.

This dissertation presents and compares two methods to value the stock of human capital. One method treats the earnings of the population as if they were returns on a capital instrument, substitutes cross-section data on earnings by age for time-series data, and capitalizes the earnings at some rate of discount. This method has been in use for almost three hundred years in various forms (Sir William Petty, Burton Weisbrod). The other method is to count up the costs expended and opportunities foregone in activities which create the human capital stock.

MICHAEL D. HURD, Ph.D. California (Berkeley) 1972. Changes in labor force participation.

DAVID G. JAQUES, Ph.D. Claremont School 1973. The academic market place for Ph.D. economists.

This thesis analyzes supply and demand flows for academic Ph.D.'s during the 1960's and early 1970's, particularly as they relate to economics. It discusses the trend toward "oversupply." The forecasting methodology is evaluated focusing on the crucial role of market parameter assumptions. Inferences, from survey data, show changes in market perspectives by formulators of the market. Differences in perspectives and reactions are shown for sub-samples such as academic ranking of school.

PAUL E. JURSA, Ph.D. Texas (Austin) 1972. A case study of the impact of out-migration and return on a southern Italian commune (and province).

After stating that one possible solution to the problems of depressed areas is the out-migration and return of a portion of the area's excess population, I construct a model of the impact of out-migration and return on depressed areas. After illustrating the push-pull factors which stimulate out-migration and characteristics of southern Italian out-migration and return, the experiences of a southern Italian commune and province are examined.

WILLIAM J. KAHLEY, Ph.D. Pennsylvania State 1972. Family planning in Colombia: An analysis of cost and achievement.

RICHARD L. KALUZNY, Ph.D. Wisconsin (Madison) 1973. The determinants of household migration: The poor and the nonpoor.

The study examines the migration behavior of households during 1968–69 and 1969–70. A linear probability model is developed using measures for the expected gain from migration, household income, and other demographic characteristics. The initial analysis groups households by role. Subsequent analysis groups households by four poverty levels. Differential responses to migration determinants by poverty level are noted. The model is most successful in explaining the behavior of the poorest households, and least successful when applied to the very rich.

TIM D KANE, Ph.D. Texas (Austin) 1972. The effect of labor market change upon the employment of low-income Mexican Americans: The San Antonio experience.

This study estimates the impact of structural change upon the labor market in San Antonio, Texas between 1963 and 1969. Occupational estimates of the changing pattern of the demand for labor were compared to the occupations in which training with federal subsidy was provided under the Manpower Development and Training Act.

NABIL KHALDI, Ph.D. Southern Methodist 1973. The productive value of education in the U.S. agriculture, 1964 (a cross-section study).

The objective of this dissertation is to measure the productive value of the education of farmers resulting both from a "worker effect" and an "allocative effect." The worker effect is obtained from an estimate of the agriculture production function. The optimum value of inputs is then derived from the estimated production function and the deviations of observed inputs from this optimum are regressed on the schooling of farm manager, research activity, and

farm size with all data on a state average basis. The data of the 1964 U.S. Census of Agriculture are used. Results show both worker and allocative effects are statistically significant and positive.

LARRY L. KISER, Ph.D. Rutgers 1972. Economic efficiency and public vocational rehabilitation policy.

A public finance-human capital theoretical framework suggests the basic rationale for government to intervene in the vocational rehabilitation of disabled persons—the efficient allocation of resources toward rehabilitation and the redistribution of income toward disabled people. This study attempts to assess the concern for efficient allocation of resources by analyzing individual case and state by state data. The results suggest that economic efficiency is an important concern of the public program.

THOMAS A. KOCHAN, Ph.D. Wisconsin (Madison) 1972. Internal conflict and multilateral bargaining in city governments.

A behavioral model of the city government collective bargaining process is developed and tested. The model is based on the assumption that there is a close relationship between the nature of the internal city management decision-making process and the union management collective bargaining process. The major proposition in the model is that the more conflict that occurs among city officials, the more multilateral bargaining that occurs. A nationwide sample of 380 cities that bargain with locals of the International Association of Fire Fighters provided the empirical basis for testing the model.

EDY L. KOGUT, Ph.D. Chicago 1972. The economic analysis of demographic phenomena: A case study for Brazil.

The study deals with certain demographic phenomena peculiar to Brazil, particularly the existence of different types of marriage. Characteristics of the populations in each type of marriage (such as schooling, income, age) are compared. The characteristics of the different types of marriage themselves (such as duration, age at marriage, stability) are also compared. These characteristics suggest the reasons for different choices made by different individuals.

ANDREW I. KOHEN, Ph.D. Ohio State 1973. Determinants of early labor market success among young men: Race, ability, quantity and quality of schooling.

This study tests a series of hypotheses regarding the determinants of early labor market success among out-of-school young men, where the principal measures of "success" are hourly earnings and social status of occupation. The hypotheses are exhibited in a three-equation, recursive model, and focus mainly on intercolor differences in success and the relative importance of schooling and ability. The hypotheses are tested by multiple regression analyses of data from the National Longitudinal Surveys of Labor Market Experience.

PAULINE W. KOPECKY, Ph.D. Houston 1972. The geographic mobility of American economists.

This study is a longitudinal analysis of the migration patterns of a matched sample of 5,412 economists. Two experiments, utilizing regression analysis, investigate the mover-stayer status, and the salary differential from 1964 to 1968. The third experiment uses a gross flows of labor model to determine the direction and magnitude of migration of these economists. Empirical results are then analyzed in relation to the theoretical hypotheses set forth in the geographic mobility model for professional workers. The findings show little difference in the eight observed characteristics of the migrants and nonmigrants; age was of minor importance; and *ceteris paribus* movers receive higher salaries than stayers.

ROGER LAMM, Ph.D. California (Berkeley) 1973. Black union leaders at the local level.

LEE A. LILLARD III, Ph.D. North Carolina State 1973. An explicit solution to the human capital life cycle of earnings model and its application to earnings distributions.

A solution to a life cycle model was used to guide study of earnings and distribution. An earnings function was estimated using IRSS-Eckland data on high school sophomores in 1955 who took achievement tests and responded to a 1970 survey. The function is used to derive earnings distributions. These distributions display the usual skewness. Specific results included: mean and variance of earnings increase with an increase in age; and an increase in schooling increases earnings dispersion.

DARRYL W. LOWRY, Ph.D. California (Berkeley) 1972. The selective migration bias in labor force participation rates.

ROBERT J. MCINTYRE, Ph.D. North Carolina (Chapel Hill) 1972. Nature and causes of the fertility decline in eastern Europe: Structural change and abortion reform from 1955 to 1968.

JANICE F. MADDEN, Ph.D. Duke 1972. The economics of sex discrimination.

JAMES N. MANGUM, Ph.D. Oklahoma State 1972. An empirical analysis of the relation between personal attributes and the duration of unemployment.

The purpose of this dissertation is to test hypotheses regarding the relation between selected personal characteristics and the duration of unemployment. Special emphasis is given to identifying those factors that are associated with relatively longer periods of unemployment. The sample used in the study is composed of several thousand unemployment insurance recipients who received benefits through a single Brooklyn, New York insurance office between August 28, 1967 and January 3, 1969.

WILLIAM L. MARR, Ph.D. Western Ontario 1973. The

economic impact of Canadian inward and outward migration and their determinants, 1950–1967.

This study examines the economic determinants of inward and outward migration for Canada, 1950–1967. It develops the hypothesis that income and labor market conditions in sending, receiving, and competing countries determine migration flows. I find that Canadian labor market conditions and income prospects influence inward, but not outward migration; that these influences in the sending country are unimportant, and that income prospects in competing countries affects inward migration.

EARL A. MOLANDER, Ph.D. California (Berkeley) 1972. The ideology of aerospace program managers.

JURGEN MULERT, Ph.D. Colorado State 1972. Labor-management conflict resolution.

The literature contains numerous analyses of particular elements of distribution, wage, and bargaining theory conceived as expressions of labor-management conflict. This thesis shows the fruitfulness of this approach in a systematic and comprehensive manner by applying it to the major schools and developments in the history of economic thought.

MAZIN M. NASHIF, Ph.D. Nebraska 1972. An interpretive analysis of labor productivity in selected Nebraska manufacturing industries, 1958–1967.

The study attempted to determine dominant causes of labor productivity movements in sixteen Nebraska manufacturing industries. Broad categories of causes of advances in labor productivity were noted and causal hypotheses were constructed. Cross-sectional correlation and regression analysis were employed to test these hypotheses. The analysis confirmed the hypotheses that productivity movements were attributed mainly to highly labor-saving technical advances and to factor substitution.

ROBERT E. OTLEWSKI, Ph.D. Indiana 1972. Economic and psychological analysis of labor mobility: A study of the Indiana secondary school teacher.

This study focuses on the mobility experience of male secondary teachers in the public schools of Indiana and is restricted to nonoccupational geographic job changes of experienced teachers. Its major objective was to examine and integrate into a model of labor market behavior those noneconomic parameters which affect the incidence and pattern of mobility. The mobility experience of teachers also offers the opportunity to examine the allocative mechanism of a specific labor market.

JOHN PAPADAKIS, Ph.D. Clark 1972. On a theory of the staffing ratio: The relation of clerical staff to blue-collar workers in Greek manufacturing.

The concept of an "Operative Staff Function" is proposed as a way to determine the extent to which the composition of labor force affects the efficiency of industrial firms. The model is applied to fourteen Greek manufacturing industries. The way in which the staffing ratio affects productivity differs between industries. Appropriate adjustments in the composition of labor force may increase overall efficiency in a given economic environment without further increases in the use of resources.

ANTHONY C. PETTO, Ph.D. Missouri 1972. An economic analysis of migration for the Ozarks.

This study examines factors influencing out- and in-migration into the Ozarks region during the 1950 and 1960 decades and also the impact of net migration on the growth of per capita income for Ozark counties. An important finding was that out-migration was primarily determined by economic conditions within the Ozarks region and by noneconomic factors at destination areas. Single equation and simultaneous equation models were utilized.

R. H. M. PLAIN, Ph.D. Alberta 1972. Interregional and interindustry differences in the elasticity of factor substitution and the efficiency of labor in Canada.

RALPH A. PURVES, Ph.D. California (Berkeley) 1972. Interstate migration, demographic trends and regional employment growth: An analysis of recent migration to California.

GARY C. RAFFAELE, D.B.A. Harvard 1973. Background and early history of the international organization of masters, mates, and pilots (AFL-CIO).

This study partially fills a void in maritime history by concentrating on the oldest union of deck officers. It is the result of the author's unlimited access to the organization's historical records. A general background of the traditions and legal environment is given. Emphasis is placed on providing a definitive history of the organization from 1880 to 1930. It was found that general theories of the American labor movement were not completely applicable to this organization.

ALI REZA, Ph.D. California (Berkeley) 1973. A study of employment functions and changes in their structure.

WALTER E. RICE, Ph.D. Claremont School 1973. Employment, unemployment and labor force participation of the rural resident poor—a case study of southern San Luis Obispo County, California.

The basic hypothesis tested is that causes of poverty—limited educational opportunity, prejudice, ill health and a lack of family and labor mobility—are the same for the rural and urban poor. By use of a randomly administered questionnaire amongst rural resident poverty population it was determined that for the South County Planning District of San Luis Obispo County, California, the poverty problem was caused by an excessive supply of low skilled workers who maintained residence because of nonjob considerations in the area.

STEVEN C SALOP, Ph.D. Yale 1972. Wage differentials and unemployment.

MICHAEL J. SATTINGER, Ph.D. Carnegie-Mellon 1973. Two-part tariffs, human capital and nursing.

PHILIP M. SCHERER, Ph.D. Missouri 1972. Rural southern residents and the incentives to work.

This dissertation analyzes the effect of the welfare institution on the incentive to work and whether economic dependency is being generated by this institution. By means of a household survey, the rural heads of households are queried concerning eight values which could affect attitudes toward work. Responses are analyzed by three main categories of respondents—the welfare recipient, the nonwelfare poor, and the nonwelfare nonpoor—and selected demographic characteristics.

RICHARD E. SCHOENBERGER, Ph.D. Clark 1973. The determination of Wisconsin teacher salaries under conditions of bilateral monopoly: Some econometric evidence.

In recent years, two important changes have taken place in the Wisconsin teacher market. School districts have become substantially fewer while school teachers have begun bargaining collectively. Three changes have restricted competition from both the buyer and seller sides of the market; therefore, monopoly and monopsony are important factors in the determination of Wisconsin teacher salaries. This conclusion is based on the empirical evidence resulting from the construction and estimation of a bilateral monopoly model.

ELI SEGEV, D.B.A. Harvard 1973. Environmental analysis and decision making: A case study in the manpower area.

A study of the use of environmental analysis in the decision-making process (related to manpower), based on field research done in Israel. It proposes a dynamic approach to manpower analysis. This study demonstrates the need to change the perception of manpower on the part of environmental analyzers and decision makers from a semistatic manpower "pool" to a concept which recognizes that manpower is a subsystem of the larger environment and that it is dynamic in nature.

WILLIAM J. SEROW, Ph.D. Duke 1972. Economic and demographic implications of a stationary population: A case study of the United States.

RICHARD L. SHORTLIDGE, JR., Ph.D. Cornell 1973. The employment and earnings of agricultural graduates in India: A benefit cost case study of G. B. Pant College of Agriculture and Technology.

A cost-benefit analysis of India's initial agriculture university. Benefits are based on data from a questionnaire mailed to all graduates, and costs are based on official university student and budget accounts. Earnings profiles were computed using single equation multiple regression techniques. The study shows high rate of social and private returns; low unemployment rates; a particularly effective program of degree training of village level workers; high return to private and quasi-public employment relative to state government employment.

JAMES P. SMITH, Ph.D. Chicago 1972. The life cycle allocation of time in a family context.

A model is developed to explain the timing of market work of family members. The model shows that hours of work of each family member is determined by variations in price of time of both members, the rate of interest and time preference, and changes in the technology of household production in the course of the aging process. The model is tested using 1967 *SEO* data.

LARRY J. SMITH, Ph.D. Chicago 1973. Black-white reproductive behavior: An economic interpretation.

Utilizes 1967 Survey of Economic Opportunity data to apply the New Economics of the Family" (*NEF*) to analysis of Children Ever Born (*CEB*) by race and census region. The perspective provided by the *NEF* does not "explain" black-white differences in *CEB*, but interesting differences between the races in the relationships between education, wife's wage, income and family wealth and *CEB* are identified and documented by replication across census region.

RICHARD B. SMITH, Ph.D. Iowa State 1972. Pay packages and employment conditions of farm employees in eastern Iowa.

Study focused upon possible reasons for problems of hiring full-time farm labor. Labor management attitudes of farm employers were found to be significantly related to employee turnover and tenure. Employee status as reflected in titles was usually unattractive. Pay package design lacked competitiveness as some common nonfarm benefits were desired more often than received. Employee pay level was below average manufacturing wages. However, pay level was not found significantly related to employee turnover and tenure.

MICHAEL W. STEBBINS, Ph.D. California (Berkeley) 1972. The social science Ph.D. in corporate industry.

EDWARD I. STEINBERG, Ph.D. New York 1973. Upward mobility of low-income workers.

Using data from the continuous Work History File of the Social Security Administration, this study analyzes the firm- and industry-attachment patterns, and the upward mobility patterns, of various demographic groups in the low-income work force between 1965 and 1970. The study focuses, too, on the effects of such variables as firm size and industry growth on worker attachment and advancement, and on upward mobility in three industries in New York City—apparel, banking, and general merchandise stores.

STANLEY P. STEPHENSON, Ph.D. Indiana 1973. Economics of job search: A biracial analysis of job search behavior of urban male youth ages 18–22.

A basic premise of this study is that lack of job search information to youth entering the labor market, especially black youth, increases youth unemployment, and contributes to black/white differences in earnings, unemployment, and mobility. To examine this premise this study developed a simultaneous equation model of job search. The model contained four equations and twenty-four variables, and used survey data of 150 white and 150 black, young, urban, unemployed men in Indianapolis during November, 1971.

GELVIN L. STEVENSON, Ph.D. Washington (St. Louis) 1973. Determinants of the occupational employment of black and white male teenagers.

A theory of heterogeneous labor inputs takes account of (mis)perceptions and subjective and objective aspects of labor supply and demand. This provides theoretical underpinnings for labor market queue analysis. Regressions (1960 Census data) test for determinants of aggregate and occupational shares (and differences in shares) of black and white males 18–19 years old. Competition between these two groups occurs only in service and labor. Structural factors and racial attitudes are important determinants of occupational shares.

VICTOR C. TABBUSH, Ph.D. California (Los Angeles) 1973. Manufacturers' assistance in the provision of training of employees of customer-firms: Theory and a case study.

This study investigates a phenomenon previously ignored in the economic literature: the provision of training by manufacturers to the employees of client-firms. The hypothesis employed to explain this form of investment is that training may raise not only a worker's productivity, but also the value placed on the resources for which the training is developed. The hypothesis is tested by investigating the mechanic-training behavior of manufacturers in the automobile industry.

BEN B. TARWATER, Ph.D. Missouri 1972. The market theory of union growth: A special case of strategic position in the structure of markets.

THOMAS E. TILL, Ph.D. Texas (Austin) 1972. Rural industrialization and southern rural poverty: Patterns of labor demand in southern nonmetropolitan labor markets and their impact on the poor, 1959–1969.

A 100 percent example of southern counties is used to examine the extent of nonfarm job growth in southern nonmetro labor markets in the 1960's. Then a 147 county sample from 10 states is drawn to determine which industries are growing and declining in nonmetro areas and why. Finally, four Mississippi nonmetro counties are chosen for a study of the impact of rural industrialization on the poor.

ALDON A. TURNER, Ph.D. North Carolina State 1972. An empirical investigation of search techniques used by job searchers.

The purpose of this research was to determine which of the two search models presented in the literature, order statistic and sequential search, better explained the search behavior of job seekers. Several tests were developed to differentiate between the two modes of search. The results tend to justify the assumption of sequential search made by several authors studying the Phillips curve.

MANHARLAL D. VYAR, Ph.D. Pittsburgh 1971. Planning for universal primary education under alternative assumptions of fertility patterns and target dates.

DAVID R. WHIPPLE, JR., Ph.D. Kansas 1972. A generalized theory of job search.

A job search model is constructed incorporating previously ignored features such as a non-linear utility function, endogenously changeable job skills, a career time horizon, a preference for the "kind" of work done, and a modified effect of search. Then the optimal vector of decision variables, namely the acceptance wage and the rate of saving and search, is characterized. Using the information generated by the model, comparisons with the existing literature are made and the significance of differences noted.

WALTER E. WILLIAMS, PhD. California (Los Angeles) 1972. The low-income market place.

Exploitation is a frequently offered hypothesis used to account for observed differences in retail activity between high- and low-income areas. This dissertation offers an alternative hypothesis that these differences can be attributed to merchant wealth-maximizing adaptive response to low-income areas. Models are developed to account for differences in household behavior based on income differences; these models form the basis for the analysis of merchant behavior in low-income areas.

DAVID A. WISE, Ph.D. California 1972. Academic achievement and job performance: Earnings and promotions.

Welfare Programs; Consumer Economics; Urban and Regional Economics

DAVID A. AMEEN, Ph.D. Maryland 1973. An analysis of the welfare economic consequences of forced busing.

The purpose of this thesis is to demonstrate that economic analysis can be fruitfully applied to public policy issues even where distributional or political considerations are involved. Consequently, a model was developed for analyzing the welfare economic consequences of a social issue confronting our society today; namely, the issue of forced busing. To demonstrate applicability, the model was used to evaluate the distributional costs and benefits of forced busing for a particular locality—Richmond, Virginia.

KENNETH L. AVIO, Ph.D. Purdue 1972. Two topics in applied microeconomics: Criminal correction policies and statutory interest rate ceilings on consumer loans.

Two policy problems are discussed. Part one presents a model of a prison as a multi-product firm. Optimal correction policies are developed, with rehabilitative training included as a control variable. Part two presents a model of high-risk loan markets. The supply side is represented by a synthesis of Tobin-Markowitz and safety-first portfolio models. Effects of rate ceilings on the price-volume-credit risk structure of loan markets are derived, with application to adoption of the *UCCC*.

SUSAN A. BIES, Ph.D. Northwestern 1972. Commercial banking in metropolitan areas: A study of the Chicago *SMSA*.

The purpose of this study was to develop a model of the distribution of commercial banking activity within metropolitan areas. Population, income, age, nonmanufacturing employment, and size of the bank and its distance to the *CBD* were found to be positively related to demand. Number of competing banks in adjacent subareas, percentage of population nonwhite, and the ratio of employment to population in a subarea were negatively related to demands.

KEITH E. BERNARD, Ph.D. Maryland 1972. A long term projection of the black-white income gap.

This study projects black and white incomes to the year 2000 on the basis of current occupational distributions. Numbers of income projections are made corresponding to various degrees of occupational discrimination. Racial education differences are projected to narrow but still be substantial by the year 2000. Even in a nondiscriminatory situation, a significant gap between white and black incomes is projected to exist by the end of this century.

DOUGLAS E. BOOTH, Ph.D. Washington 1972. On residential location and the provision of local public goods in metropolitan area.

DALE O. CLONINGER, J.B.A. Florida State 1973. An economic analysis of the relationship between law enforcement rates and the rates of certain criminal activities.

This study takes as its objective the analytical and empirical determination of the relationship between law enforcement and the rates of certain criminal activities. It was found that levels of enforcement are positively associated with levels of criminal activities using cross-sectional data. However, the positive association disappears and becomes negative for most crimes studied when changes in enforcement are associated with changes in crime rates. Serious errors of specification "cloud" the empirical results.

CAROLINE P. CLOTFELTER, Ph.D. Alabama (Tuscaloosa) 1973. Giffin Bonds for minority development.

This study incorporates a neglected aspect of minority behavior in a theoretical and empirical approach to autonomous capitalism. The premise is that discrimination increases the group-identification of minority individuals and thus decreases their risk aversion toward group investment. Consequently they represent a potential source of low-cost development capital, or what is called Giffin Bonds. A case study of Israel Bonds and findings on deviant Negro spending patterns lend support to the theory.

WILLIAM E. COBB, Ph.D. Virginia Polytechnic Institute 1973. The economics of shoplifting.

Criminal offenses were said to be a function of probability of apprehension, punishment, a portmanteau variable representing alternative income sources, moral turpitude, etc., and the perception the potential criminal possesses about these variables. Shoplifting was examined first from the standpoint of the retail merchant and the potential shoplifter. It was shown that a profit-maximizing retailer neither should nor does attempt to alter the first three variables included in the offense function, but that the merchant does attempt to affect the thief's perceptions.

STEPHEN COELEN, Ph.D. Syracuse 1973. A model for measuring the benefits of public investment in urban areas: Theory and measurement.

This study attempts to evaluate, both theoretically and empirically, the relationship between water supply and sewerage system investments and land values. The theoretical model is developed in the early sections of the paper. A case study on water and sewerage investments in Nairobi, Kenya is then presented as an initial test of the model.

RICHARD B. COFFMAN, Ph.D. Washington 1972. The economics of fluoridation.

LESTER R. COHEN, Ph.D. California (Los Angeles) 1973. A time allocation model of residential equilibrium.

This research develops a microtheoretical model describing residential behavior, taking into account the influence of time upon utility maximization in the context of all family consumption and labor supply activities. The household is considered to behave as an economy unto itself with interdependent consumption and production sectors, allocating time and capital according to factor and product market efficiency criteria. Included are critiques of the Muth model of residential equilibrium and Becker's theory of time allocation.

KENNETH A. CONEY, Ph.D. Oregon 1973. Consumer information processing: Organization of product comparison information through the cognitive principle of leveling-sharpening.

ANNA M. CRAIG, Ph.D. Wisconsin (Madison). The distributive impact of urban renewal programs: A case study, Hyde Park A and Hyde Park B.

Two Chicago urban renewal clearance and redevelopment projects were analyzed. In these cases, land acquisition and disposition had little redistributive impact. However, prerenewal tenants suffered large net losses relative to their incomes. The major beneficiary was the city government, although because of taxpayer contributions to the federal cost of these and all other federally assisted urban renewal projects, the benefits to the city's citizens was substantially less.

CHARLES B. DANIELS, Ph.D. Stanford 1973. An investigation of the influence of racial segregation on housing prices in the Oakland, California housing market.

Using a regression model, this study examines the relationship between housing prices and residential segregation in a California housing market with data from the 1960. Census and a 1965 land-use survey. White renters paid a segregation premium to live in the white submarket, implying competition rather than collusion in the rental housing market; a unit of housing space was more expensive in the black market while a unit of housing quality cost more in the white submarket; and home owners pay premiums for sites farther from the city central business district where blacks are concentrated. Legislatively imposed quota systems or financial incentives would be more effective than antidiscrimination legislation in reducing residential segregation.

SIDNEY DAVIS, Ph.D. Georgia State 1973. Household consumption of housing service flows in Atlanta, Georgia.

This study examines consumer demand for housing service flows which are represented by the utility derived from a dwelling unit that has the following characteristics: a specific spatial location in the urban community; a specific vector of physical attributes including size and quality, in combination with a quantity of "transportation," enabling the household to participate in activities taking place in locations removed from the place of residence. The housing service flow concept then serves as the basis for a simultaneous equation model.

FRANCIS J. EGAN, Ph.D. Fordham 1973. Air pollution and property values in the Hartford metropolitan region.

This dissertation investigates the relationship between air pollution and residential property values in the greater Hartford metropolitan region. To measure this relationship, a single equation, linear regression model is constructed with property values as the dependent variable and air pollution as one of the independent variables. Census tracts are chosen as the basic units of observation.

JAMES A. M. ELLIOTT, Ph.D. Yale 1972. International comparisons of social welfare: A factor analytic approach.

MICHAEL C. ELLIS, Ph.D. Alabama 1973. An empirical and methodological approach to the relationship between regional income inequality and economic development: A study of the Ozark region in 1970.

A significant and sometimes unforeseen consequence of regional development programs is an increase in the inequality of personal income. In order to ascertain whether a growth-income inequality tradeoff exists for the Ozark region, the area was analyzed cross-sectionally in 1970 to determine: the extent of family income inequality; the major principal component dimensions of development; and the relationship between family income inequality and economic development.

DONALD R. EPLEY, Ph.D. Missouri 1972. A test of base theory using income and employment.

This study developed for the state of Missouri four Laspeyres indices which were incorporated into base theory. Two indices measured income and employment fluctuations for the basic sector and the other two, the nonbasic sector. Index components and weights were determined from the state input-output table. Results revealed that base theory in income terms has no relationship to base theory in employment terms. The roles of the employment indices were reversed.

CHARLES L. FRANCE, Ph.D. West Virginia 1972. A production model of a large city police department.

AL FRANCFORT, Ph.D. Pittsburgh 1972. Driving without a steering wheel—the need for and use of health statistics in economic analysis.

The central objective of this study is to suggest what should be done to obtain the health information needed to achieve a better allocation of resources both *to* and *within* the health sector of the economy. The premise is that the health statistics currently available are inadequate. The study suggests possible improvements in the health information system which should result in additional benefits to health care and increased levels of healthiness in the population.

RICHARD T. FOX, Ph.D. West Virginia 1973. The cost of selected hospital services.

LEE S. FRIEDMAN, Ph.D. Yale 1973. Innovation and diffusion in non-markets: Case studies in criminal justice.

WILLIAM C. GIAUQUE, D.B.A. Harvard 1972. Prevention and treatment of Streptococcal sore throat and rheumatic fever—a decision theoretic approach.

In this research the medical problem of prevention and treatment of Streptococcal sore throat and rheumatic fever was examined and alternative treatment strategies evaluated. Methods of decision theory and multivariate utility theory were used to structure the problem and define an objective function. A procedure to determine parameters of the utility structure was determined and applied to patients, doctors, nurses, and public health officials. Implications of results for clinical practice were discussed.

STEVEN D. GOLD, Ph.D. Michigan 1972. The distribution of recreation services in Detroit 1968–69.

RONALD E. GRIESON, Ph.D. Rochester 1973. Essays in urban economics and public finance.

"The incidence of profits taxes in neoclassical growth model" is a theoretical study of the effect of taxes on the capital-labor ratio, and on the long-run wage, net of taxes. "The economics of property taxes and land values" is a simultaneous model of land values, uses, and gradients; elasticities of supply, price, and densities of structure. "The determinants of juvenile arrests" is an econometric estimate of the effects of social and economic programs.

JOHN A. HANSON, Ph.D. Oregon 1972. A vintage capital model of urban development.

ROBERT G. HEALY, Ph.D. California (Los Angeles) 1972. Agglomeration and footlooseness: The distribution of economic activities among metropolitan areas.

The dissertation deals with the spatial agglomeration of industries, both manufacturing and nonmanufacturing, in 203 metropolitan areas. Factor analysis is used to divide 186 industries into groups which have the property that cities specialized in one industry are likely to also specialize in the others. The role of backward and forward linkages in producing agglomerations is explored and a regression model is used to identify the dominant locational forces for each of several selected industries.

THOMAS L. HEFLIN, Ph.D. Oregon 1973. The prediction of retirement adjustment.

FREDERICK J. HITZHUSEN, Ph.D. Cornell 1972. Some policy implications for improved measurement of local government service output and costs: The case of fire protection.

This study uses a multiple curvilinear regression analysis of fire protection unit costs and output (people and property protected) in 150 Texas and New York localities. Costs include not only public sector current expenditure but estimates of public capital costs, public water supply costs and unpaid volunteer time contributed. A benefit-cost analysis provided estimates of tradeoffs between public fire protection improvements and private fire insurance savings.

JOHN H. HOAG, Ph.D. Kansas 1972. The economics of the health service industry.

The dissertation reports on an economic model of the model to two problems relating to the allocation of resources in this market. The model is an aggregate general equilibrium model involving four sectors—consumers, doctors, hospitals, and insurance. The first application deals with the effect of insurance on the consumer's choices; the second is an investigation of the relationship of the doctor and the hospital.

PETER M. HUTCHINSON, Ph.D. Pittsburgh 1972. Accessability and segregation: Their effects on the employment of the urban poor.

The dissertation uses a linear probability model based on observations of poverty zone residents in the Pittsburgh region to determine how housing segregation and employment accessibility affect the probability of poverty area residents being employed. Results of the empirical tests suggest that improved public transit in the form of a dial-a-bus or a program of providing automobiles for the poor may significantly improve employment prospects for the urban poor. On the other hand, ghetto dispersal policies aimed at eliminating housing segregation does not improve employment possibilities.

LEONARD W. KATZ, D.B.A. George Washington 1972. An evaluation of the state of Connecticut Health and Educational Facilities Authority's impact on the provision of nongovernmental health facilities.

Compared to other reported long-term borrowing, authority tax-exempt revenue bond financing provided hospitals with lower interest rates and cost of capital and longer maturities. Debt principal equalled between 60 and 93 percent of total costs. Hospitals borrowed 36.9 to 89.8 percent of projected debt capacity. Debt servicing might be adversely affected if third party reimbursement declines or the construction period extends materially beyond the expected completion date.

WERNER KIENE, Ph.D. Michigan State 1972. Evaluation of the impact of health care on activity levels of the rural poor.

NEIL KOMESAR, Ph.D. Chicago 1973. Economic analysis of criminal victimization.

PETER J. KUCH, Ph.D. Minnesota 1972. A planning for postsecondary education in west central Minnesota.

This study is concerned with planning the efficient development of postsecondary education in a region. Attention is focused on allocating public resources among competing curricula and institutions, where primary concern is on the pecuniary returns to schooling. The procedure employed uses multi-period linear-programming models which maximize the net social benefits generated by the postsecondary system subject to constraints describing the educational technology available to the region and externally imposed policy decisions.

HAROLD LUFT, Ph.D. Harvard 1973. Poverty and health: An empirical investigation of the economic interactions.

This study provides estimates of the probability of disability based on age, race, sex, education, and predisability income and detailed working conditions. The second half derives estimates of earnings and income losses attributable to disability, as well as the share of poverty caused by poor health. Serious specification errors are demonstrated in labor force equa-

tions without health status. Aggregate and individual data are drawn from the 1967 *SEO* and 1966 Survey of Disabled Adults.

KENNETH E. MCCONNELL, JR., Ph.D. Maryland 1973. Estimating consumer demand functions from cross-section data.

Cross-section estimates of consumer demand functions, though valuable because they are devoid of problems of autocorrelated errors, have been rare because of the absence of price variations in cross-section data. This study attempts to overcome the problem of no price variation. Price elasticities from directly and indirectly additive utility functions are computed by (1) estimating consumers' responses to different wage rates; (2) imposing second-order conditions on structural parameters. Results from elasticities computed from a group of *SMSA's* demonstrate that such elasticities can be useful.

PATRICK A. MCGUIRE, Ph.D. Fordham 1973. A simulation model of the Rochester, New York region.

The object of this study is to develop a simulation model for an urban area. The model will attempt to illustrate the effectiveness of various policy changes on the theoretical city. The objective is to demonstrate that traditional policy recommendations may not be as successful in the long run as expected. The model will be applied to a particular city to illustrate the long-run effects of policy changes.

PETER J. MCMAHON, Ph.D. Southern California 1972. Forecasting selected statewide recreation requirements.

This study develops an approach to forecasting outdoor recreation demand and supply requirements. To provide the background for the approach, the study first analyzes the nature of the recreation market as well as the difficulties, methods used, and relevant factors in making these projections. An empirical model is then formulated using microeconomic constructs to enable forecasts of recreation demand and optimum combinations of selected recreation facilities that must be supplied to meet this demand.

JOHN C. MCPHERSON, Ph.D. Brown 1973. The economics of central place hierarchies: Applications to the great plains experience.

This thesis presents a formal view of the economic structure of urban centers in terms of their spatial, size and frequency distribution. A generalized hierarchy model is formulated as a set of difference equations with explicit spatial and nonspatial parameters, and an explicit solution obtained. Within this framework the parametric differences between Canadian and American great plains economies in 1960–61 are examined, along with the change in spatial parameters in Saskatchewan 1941–61.

JOSEPH P. MAGADDINO, Ph.D. Virginia Polytechnic Institute 1973. An economic analysis of state gun control laws: A statistical study of 1970 data.

The problem of firearm misuse was defined on the basis of an externality argument. To test the efficacy of gun control laws, a cross-sectional study of supply of offenses was conducted. This study attempted to explain the differences in crime rates among states attributable to differences in the level of deterrence, and the gun control laws while accounting for differences in socio-demographic variables.

ADELE P. MASSELL, Ph.D. Stanford 1972. A bimarket analysis of the urban labor market.

This study analyzes change in the location of new plants in suburban areas surrounding central cities, to determine its effect on employment. The economic implications of alternative intraurban spatial configurations of employment are made through a partial-equilibrium, comparative statics model, with two interdependent labor zones. Both central and suburban workers are best off when the spatial distribution of firms parallels that of workers' residences. When racial variables as proxies for labor skill variation are included in the model, results suggest that when firms suburbanize white central and suburban residents tend to benefit but that central nonwhites face lower wages.

MARSHALL H. MEDOFF, Ph.D. California (Berkeley) 1973. A theoretical and positive analysis of discrimination in the market place.

STEPHEN L. MEHAY, Ph.D. California (Los Angeles) 1973. Production functions for crime-deterrent police services.

This study is a theoretical and empirical investigation of the production of crime-deterrent services by urban police departments. A model of police protection output is developed and estimated using cross-section data from southern California police departments.

EMIL MEURER, Ph.D. Nebraska 1972. Crime compensation as an emerging form of social insurance.

This investigation was made to determine the extent and nature of existing state and proposed federal programs designed to alleviate the financial burden of violent crime on the victim. Status of violent crime victim is reviewed and present legislation is evaluated with recommendations for improvements.

JAMES E. MILLER, Ph.D. Texas A&M 1973. Analytical and operational aspects of central facilities location.

The objective of this study is to adapt traditional private facility location theory for central public facility location. The conclusions are as follows: the location theory of Alfred Weber, as a basis for certain operational techniques (e.g., spatial combinatorial programming) may be successfully applied to only small scale problems involving emergency facility location; and Löschian market area theory as a basis for developing an analytical model with the opportunity costs of user travel time introduced as a demand parameter, is a more promising approach.

WILLIAM G. MOSS, Ph.D. California (Berkeley) 1973. The effect of housing segregation on the Negro journey to work.

DAVID H. MUDARRI, Ph.D. Michigan 1972. Mode choice for work trips: A key urban transportation problem.

EDWARD H. MURPHY, Ph.D. Rutgers 1973. The market for disability insurance benefits.

The thesis analyzes the nature of the relationship between the economic environment and the market for disability insurance benefits. A theory of the demand for benefits is derived and tested for several segments of the disabled population.

JAMES A. MURRAY, Ph.D. Oregon 1972. The economics of medical care: a theoretical analysis.

This dissertation presents a positive microeconomic theory of the production and use of medical care. A primary objective is to determine the significance of well-known product and institutional peculiarities. Standard optimization techniques are used to develop theorems from a set of behavioral hypotheses. These theorems describe how pricing and utilization of physicians' and hospital services relate to factor prices, patient incomes and insurance coverage. Results obtained differ importantly from theorems of neoclassical models.

TIM O. OZENNE, Ph.D. California (Los Angeles) 1972. The economics of theft and security choice.

Theft is controlled not only by governmental actions but also by private security choice. This study develops a model of theft in which the rate of theft is determined jointly with optimal security expenditures. The model is then used to explain variation in bank robbery rates across states and over time. The empirical results conform with the theoretical implications and show that earnings net of imprisonment costs have the anticipated effect on robbery behavior.

RICHARD B. PARKER, Ph.D. Boston College 1973. Interregional income distribution, factor migration, and growth.

Analysis, parameter estimation, and computer simulation of dynamic interregional models of migration and income are carried out to explore the equity-efficiency tradeoff. At very low levels of factor migration response to productivity differences, a policy which increases their response will improve interregional equity. A maximum is found, beyond which further increases in the migration-reaction coefficient result in equity loss. Below this maximum, higher growth under an equity constraint requires greater factor migration response.

PAUL U. PAWLIK, Ph.D. Arizona 1972. The effects of health fluctuations on economic activity in Iran.

The question examined is whether or not fluctuations in health, in Iran, affect individual firm's production, individual industry's production, and general economic activity. Fluctuations in health will be compared statistically to fluctuations in individual firm's production, individual industry's production, and general economic activity over a four-year period (on the monthly basis).

NORMAN E. PAYNE, Ph.D. Cornell 1973. An economic evaluation of school lunch systems.

With school lunch programs receiving increasing attention for social and nutritional reasons this research focused upon the basic economic aspects of alternative systems. Wage rates and labor productivity were clearly the most important factors causing variations in the cost of providing a school lunch in seven eastern and southern states. The type of system (unit kitchens or satellite facilities) and size of system were much less important.

ROBERT M. PETERS, Ph.D. Kentucky 1972. A study of teacher aide impact and the economics of aide usage.

JOHN G. PHOTIADES, Ph.D. Illinois (Urbana) 1972. A multivariate analysis of family income distribution of U.S. counties.

WILLIAM POLLAK, Ph.D. Princeton 1972. Public fire protection: Costs, demands, and pricing.

Suppression capability is defined as a quality measure. A priori models drawing on identified response-time/damages relationships are used to analyze the area, population, and quality dimensions of the protection cost function. A firespread model is used to analyze protection demands and the efficiency benefits of pricing protection are examined using geometric models. These show that in a dynamic setting fees may prevent an over shifting of protection burdens to the public sector.

ELIZABETH A. ROISTACHER, Ph.D. Pennsylvania 1972. The distribution of tenant benefits under rent control.

FREDERICK H. RUETER, Ph.D. Carnegie-Mellon 1973. Municipal zoning: An empirical study of its economic and political justification.

DANIEL H. SAKS, Ph.D. Princeton 1973. Economic analysis of an urban public assistance program: Aid to New York City families of dependent children in the sixties.

Using primarily survey data for New York City in 1967, creation of welfare cases was analyzed as a problem of rational choice. The welfare system was found to be a complex negative tax scheme with tax rates well under 100 percent. Plausible income and substitution parameters were estimated for supply-of-recipients, on-welfare-labor-force-particiaption, and welfare-duration equations. Welfare survival rates were estimated and shown to be Markovian.

C. JAMES SAMPLE, Ph.D. American 1972. Patterns of economic change in regions of the continental United States.

JAMES L. SHANAHAN, Ph.D. Wayne State 1972. Spatial isolation and job opportunity for low skill residents in the core of the Detroit SMSA.

TIMOTHY G. SHANAHAN, Ph.D. Purdue 1972. Equity and efficiency of alternative policies and mechanism for optimizing consumer-type levies.

RAM K. SHARMA, Ph.D. Western Ontario 1973. Benefit-cost analysis and public health: A case study of the Tuberculosis Control Program in Ontario, 1948–1966.

This dissertation develops and explains the methodology of applying benefit-cost analysis to public health projects and then applies it to a specific cases: The Tuberculosis Control Program in Ontario from 1948 to 1966. The marginal benefits and costs of the program, as measured in this study, prove that the program was a profitable use of resources even after accounting for the beneficial effects of "wonder drugs" discovered for tuberculosis treatment.

ALLAN K. SHERMAN, Ph.D. Maryland 1972. The effects of the configuration of rural health care systems on elective utilization.

MARK K. SHERWOOD, Ph.D. Purdue 1972. The demand for public and private higher education.

This thesis is a theoretical study of the choice a qualified high school graduate makes among attending a public college, attending a private college and entering the labor force.

GAD SHIFRON, Ph.D. Wisconsin (Madison) 1972. Income conditioned publicly subsidized preschool child care.

The objective of this study is to determine the economic consequences of income conditioned public subsidization of preschool child care services. It is concluded that deducting child care expenses from taxable income can be justified, but income conditioned tuition is hard to justify. It is demonstrated, on equity and efficiency considerations, that day care centers may be an expensive while not the most effective solution for improving the opportunities of mothers and children. The policy implications suggest a reconsideration of child care provisions in H.R. 1 and S-3617 (both are major bills pending in Congress at the present time).

LESTER P. SILVERMAN, Ph.D. Carnegie-Mellon 1973. The determinants of emergency and elective admission to hospitals.

JOHN C. SIMONSON, Ph.D. Wisconsin (Madison) 1972. The determinants of changes in the allocation of hospital service capacity: A study in policy theory.

LAWRENCE T. SMEDLEY, Ph.D. American 1972. The impact of a social security program and a number of other factors on household savings in a developing country: The Mexican case.

MICHAEL W. SMITH, Ph.D. North Carolina State 1972. An economic analysis of the intracity dispersion of criminal activity.

The spatial distribution of, and economic causes of, criminal activity within a metropolitan region was studied by considering the crime flows between subsections of the region. A theoretical model was developed to predict the magnitude of the import, export, and domestic production of property crime relative to a subsection. These quantities were assumed to be dependent on the income of offenders and victims of crime, the distance between subsections and the size of the subsections in terms of the number of potential offenders and victims. The results of a regression analysis indicated that the model explained a significant proportion of property crimes.

DONALD N. STEINNES, Ph.D. Northwestern 1972. An econometric model of residential location.

In this thesis a model is derived which explains the intraurban location of both residents and employment and yet is capable of being estimated from available data. Particular attention is given to the simultaneous nature of the geographic allocation of employment and residences within a metropolitan area, and to the economic-theoretic basis of these allocations. The model is estimated by *OLS* and *TSLS* using data for the Chicago metropolitan area.

STANLEY C. STEVENS, Ph.D. Illinois (Urbana) 1972. The spatial dynamics of the Chicago black community: 1958–69.

MICHAEL SUNSHINE, Ph.D. Michigan State 1973. The abuse of warranty law as a contributing factor to consumer problems.

RAYMOND J. SUPALLA, Ph.D. Michigan State 1972. The potential for increasing earned income of welfare recipients in rural areas: A case study of Allegan County, Michigan.

TATSUO R. TSUCHIGANE, Ph.D. Maryland 1972. Discrimination against women in the United States.

This study is an attempt to measure the components of discrimination against women in the economy and to identify factors affecting this discrimination. Each of the three types of discrimination, namely, income discrimination, occupational discrimination, and participation discrimination, is separated into "justified" and "unjustified" components. By separating discrimination into two components it is possible to gain insights into the extent of justified and unjustified discrimination and the prospects for removing unjustified discrimination in the future.

BRADFORD H. TUCK, Ph.D. Boston 1973. The economic impact of the petroleum sector on the state of Alaska, 1960–1970.

... IL TUDIVER, Ph.D. Michigan 1973. Why aid doesn't help: Organizing for community economic development in Central Appalachia.

MICHAEL A. VIREN, Ph.D. California (Santa Barbara) 1973. An economic analysis of the supply of medical services.

ROBERT A. WEISS, Ph.D. Wisconsin (Madison) 1972. The distribution of benefits of the Appalachian Development Highway System.

SHIRLEY F. WEISS, Ph.D. Duke 1973. New town development in the United States: Experiment in private enterpreneurship.

RAFAEL R. WESTON, Ph.D. Harvard 1972. The quality of housing in the United States, 1929–70.

Housing, like all capital goods, must be treated from the points of view of both stocks and flows, and the relationship between the two is crucial. A Divisia-hedonic model of housing indexes incorporating this distinction is developed, and empirically implemented to investigate the question of housing quality. This analysis is then employed in the creation of a complete, internally consistent, system of accounts for the housing sector of the economy.

ROBERT S. WOODWARD, Ph.D. Washington (St. Louis) 1972. Industrial incentives and regional economic growth: The case of Puerto Rico.

A priori profit impacts for each of the three intraisland industrial incentives were first estimated for typical export manufacturing firms. The empirical significance of governmental construction of standard industrial plants and extra years of tax exemption, which was indicated by profit impact calculations, was verified using promotional employment data in cross-sectional *OLS* regressions.

ANNOUNCEMENT

NOTICE TO ALL GRADUATE DEPARTMENTS

The December 1974 issue of the *Review* will carry the seventy-first list of doctoral dissertations in political economy in American universities and colleges. The list will specify doctoral degrees conferred during the academic year terminating June 1974. This announcement is an invitation to send us information for the preparation of the list. This announcement supercedes and replaces a letter which was sent annually from the managing editor's office.

The *Review* will publish in its December 1974 issue the names of those who will have been awarded the doctoral degree since June 1973, the titles of their dissertations, and, if possible, a brief (75-word) summary of the dissertation.

By June 30, please send us this information on 3×5 cards, conforming to the style shown below, one card for each individual. Please indicate by a classification number in the right-hand corner the field in which the thesis should be classified. The classification system is that used by the *Journal of Economic Literature* and printed in every issue.

JEL Classification No. ______

Name: LAST NAME IN CAPS: First Name, Initial

Institution Granting Degree: ______

Degree Conferred (Ph.D. or D.B.A.) ______ Year ______

Dissertation Title: ______

Summary

(75-word maximum, or first 75 words will be printed)

Summary may be completed on back of this card or on new card which should be stapled to this.

When degrees in economics are awarded under different names, such as Business Administration, Public Administration, or Industrial Relations, candidates in these fields whose training has been *primarily in economics* should be included.

All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.
